HANDBOOK OF

CONTEMPORARY NEUROPHARMACOLOGY

Volume 1

Edited by

David R. Sibley • Israel Hanin • Michael Kuhar • Phil Skolnick

PREFACE

Neuropharmacology is the study of drugs that affect the nervous system. This includes not only the identification of neuronal drug targets but also the study of basic mechanisms of neural function that may be amenable to pharmacological manipulation. Indeed, neuropharmacological drugs are commonly used as valuable tools to discover how nerve cells function and communicate in addition to therapeutic agents for the treatment of a wide variety of neuropsychiatric disorders. In fact, drugs that are used to treat disorders of the brain and nervous system represent one of the largest groups of approved therapeutic agents. Clearly the demand for drugs to treat disorders of the nervous system will only grow in the face of an aging population. Not surprisingly, almost all major pharmaceutical corporations and many biotechnology companies have extensive drug discovery programs in neuroscience and neuropharmacology. The recent pace of research and discovery in neuropharmacology and associated therapeutics has been quite rapid, as is true for most areas of biomedical research. Given this as well as the extremely broad nature of the field, we felt that it would be timely and important to develop a comprehensive handbook of neuropharmacology that would include state-of-art reviews covering both basic principles and novel approaches for clinical therapeutics.

Our approach for the organization of this handbook was primarily translational (bench to bedside) in nature. The three book volumes consist of 10 clinical sections, each consisting of 4–7 chapters devoted to various neuropsychiatric disorders, including mood, anxiety, and stress disorders, psychosis, pain, neurodegeneration, and many others. In most cases, these sections have introductory chapters providing background information and/or basic principles prior to presenting chapters covering state-of-the-art therapeutics. Volume I also contains a large introductory section consisting of 17 chapters on basic neuropharmacological subjects and principles. These include chapters on the history of neuropharmacology as well as intercellular and intracellular signaling followed by chapters covering all of the major neurotransmitter systems and other important signaling molecules, such as ion channels and transporters. Our objective for this project was to create a high-level reference work that will be useful to all practitioners of neuropharmacology ranging from graduate students, academicians, and clinicians to industrial scientists working in drug discovery. These volumes will be part of the John Wiley & Sons major reference work program and will be published online as well as in print. The online version of this handbook is expected to undergo frequent updates and additions in order to maintain its cutting-edge status.

The editors would like to thank all of the chapter contributors for their hard work and commitment to this project. We would also like to thank our managing editor, Jonathan Rose, at John Wiley & Sons for all of the valuable assistance that he has provided.

Contents

Preface	xi
Contributors	xiii

VOLUME 1

PART I BASIC NEUROPHARMACOLOGY	1
Chapter 1 Soup or Sparks: The History of Drugs and Synapses	3
<i>William Van der Kloot</i>	
Chapter 2 Synaptic Transmission: Intercellular Signaling	39
<i>J. David Jentsch and Robert H. Roth</i>	
Chapter 3 Synaptic Transmission: Intracellular Signaling	59
<i>R. Benjamin Free, Lisa A. Hazelwood, Yoon Namkung Michele L. Rankin, Elizabeth B. Rex, and David R. Sibley</i>	
Chapter 4 Neuronal Nicotinic Receptors: One Hundred Years of Progress	107
<i>Kenneth J. Kellar and Yingxian Xiao</i>	
Chapter 5 Muscarinic Acetylcholine Receptors	147
<i>Jürgen Wess</i>	
Chapter 6 Norepinephrine/Epinephrine	193
<i>Megan E. Kozisek and David B. Bylund</i>	
Chapter 7 Dopaminergic Neurotransmission	221
<i>John A. Schetz and David R. Sibley</i>	
Chapter 8 Serotonin Systems	257
<i>John A. Gray and Bryan L. Roth</i>	
Chapter 9 Neuropharmacology of Histamine in Brain	299
<i>Raphaël Faucard and Jean-Charles Schwartz</i>	

Chapter 10	Ionotropic Glutamate Receptors	365
	<i>David Bleakman, Andrew Alt, David Lodge, Daniel T. Monaghan, David E. Jane, and Eric S. Nisenbaum</i>	
Chapter 11	Metabotropic Glutamate Receptors	421
	<i>James A. Monn, Michael P. Johnson, and Darryle D. Schoepp</i>	
Chapter 12	Pharmacology of the GABA_A Receptor	465
	<i>Dmytro Berezhnoy, Maria C. Gravielle, and David H. Farb</i>	
Chapter 13	Metabotropic GABA Receptors	569
	<i>Martin Gassmann and Bernhard Bettler</i>	
Chapter 14	Voltage-Gated Ion Channels	617
	<i>Alex Fay, Patrick C. G. Haddick, and Lily Yeh Jan</i>	
Chapter 15	Neuropeptides	669
	<i>Fleur L. Strand</i>	
Chapter 16	Neurotransmitter Transporters	705
	<i>Jia Hu, Katherine Leitzell, Dan Wang, and Michael W. Quick</i>	
Chapter 17	Gaseous Signaling: Nitric Oxide and Carbon Monoxide as Messenger Molecules	743
	<i>Kenny K. K. Chung, Valina L. Dawson, and Ted M. Dawson</i>	
PART II	MOOD DISORDERS	763
Chapter 18	Neurobiology and Treatment of Depression	765
	<i>Alexander Neumeister, Dennis S. Charney, Gerard Sanacora, and John H. Krystal</i>	
Chapter 19	Neurotrophic Factors in Etiology and Treatment of Mood Disorders	789
	<i>Ronald S. Duman</i>	
Chapter 20	Antidepressant Treatment and Hippocampal Neurogenesis: Monoamine and Stress Hypotheses of Depression Converge	821
	<i>Alex Dranovsky and René Hen</i>	
Chapter 21	Neuroendocrine Abnormalities in Women with Depression Linked to the Reproductive Cycle	843
	<i>Barbara L. Parry, Charles J. Meliska, L. Fernando Martinez, Eva L. Maurer, Ana M. Lopez, and Diane L. Sorenson</i>	
Chapter 22	Neurobiology and Pharmacotherapy of Bipolar Disorder	859
	<i>R. H. Belmaker, G. Agam, and R. H. Lenox</i>	
Index		877
Cumulative Index		915

VOLUME 2

PART I	ANXIETY AND STRESS DISORDERS	1
Chapter 1	Neurobiology of Anxiety	3
	<i>Miklos Toth and Bojana Zupan</i>	
Chapter 2	Pharmacotherapy of Anxiety	59
	<i>Jon R. Nash and David J. Nutt</i>	
Chapter 3	Benzodiazepines	93
	<i>Hartmut Lüddens and Esa R. Korpi</i>	
Chapter 4	Neuroactive Steroids in Anxiety and Stress	133
	<i>Deborah A. Finn and Robert H. Purdy</i>	
Chapter 5	Emerging Anxiolytics: Corticotropin-Releasing Factor Receptor Antagonists	177
	<i>Dimitri E. Grigoriadis and Samuel R. J. Hoare</i>	
Chapter 6	Neurobiology and Pharmacotherapy of Obsessive-Compulsive Disorder	215
	<i>Judith L. Rapoport and Gale Inoff-Germain</i>	
PART II	SCHIZOPHRENIA AND PSYCHOSIS	249
Chapter 7	Phenomenology and Clinical Science of Schizophrenia	251
	<i>Subroto Ghose and Carol Tamminga</i>	
Chapter 8	Dopamine and Glutamate Hypotheses of Schizophrenia	283
	<i>Bitá Moghaddam and Houman Homayoun</i>	
Chapter 9	Molecular Genetics of Schizophrenia	321
	<i>Liam Carroll, Michael C. O'Donovan, and Michael J. Owen</i>	
Chapter 10	Postmortem Brain Studies: Focus on Susceptibility Genes in Schizophrenia	343
	<i>Shiny V. Mathew, Shruti N. Mitkus, Barbara K. Lipska, Thomas M. Hyde, and Joel E. Kleinman</i>	
Chapter 11	Pharmacotherapy of Schizophrenia	369
	<i>Zafar Sharif, Seiya Miyamoto, and Jeffrey A. Lieberman</i>	
Chapter 12	Atypical Antipsychotic Drugs: Mechanism of Action	411
	<i>Herbert Y. Meltzer</i>	

PART III	SUBSTANCE ABUSE AND ADDICTIVE DISORDERS	449
Chapter 13	Introduction to Addictive Disorders: Implications for Pharmacotherapies	451
	<i>Mary Jeanne Kreek</i>	
Chapter 14	Dopaminergic and GABAergic Regulation of Alcohol-Motivated Behaviors: Novel Neuroanatomical Substrates	465
	<i>Harry L. June and William J. A. Eiler II</i>	
Chapter 15	Nicotine	535
	<i>August R. Buchhalter, Reginald V. Fant, and Jack E. Henningfield</i>	
Chapter 16	Psychostimulants	567
	<i>Leonard L. Howell and Heather L. Kimmel</i>	
Chapter 17	MDMA and Other “Club Drugs”	613
	<i>M. Isabel Colado, Esther O’Shea, and A. Richard Green</i>	
Chapter 18	Marijuana: Pharmacology and Interaction with the Endocannabinoid System	659
	<i>Jenny L. Wiley and Billy R. Martin</i>	
Chapter 19	Opiates and Addiction	691
	<i>Frank J. Vocci</i>	
PART IV	PAIN	707
Chapter 20	Neuronal Pathways for Pain Processing	709
	<i>Gavril W. Pasternak and Yahong Zhang</i>	
Chapter 21	Vanilloid Receptor Pathways	727
	<i>Makoto Tominaga</i>	
Chapter 22	Opioid Receptors	745
	<i>Gavril W. Pasternak</i>	
Chapter 23	Advent of A New Generation of Antimigraine Medications	757
	<i>Ana Recober and Andrew F. Russo</i>	
	Index	779
	Cumulative Index	817
VOLUME 3		
PART I	SLEEP AND AROUSAL	1
Chapter 1	Function and Pharmacology of Circadian Clocks	3
	<i>Gabriella B. Lundkvist and Gene D. Block</i>	

Chapter 2	Melatonin Receptors in Central Nervous System	37
	<i>Margarita L. Dubocovich</i>	
Chapter 3	Narcolepsy: Neuropharmacological Aspects	79
	<i>Seiji Nishino</i>	
Chapter 4	Hypocretin/Orexin System	125
	<i>J. Gregor Sutcliffe and Luis de Lecea</i>	
Chapter 5	Prokineticins: New Pair of Regulatory Peptides	163
	<i>Michelle Y. Cheng and Qun-Yong Zhou</i>	
Chapter 6	Sedatives and Hypnotics	177
	<i>Keith A. Wafford and Paul J. Whiting</i>	
PART II	DEVELOPMENT AND DEVELOPMENTAL DISORDERS	201
Chapter 7	Regulation of Adult Neurogenesis	203
	<i>Heather A. Cameron</i>	
Chapter 8	Neurotrophic Factors	221
	<i>Franz F. Hefti and Patricia A. Walicke</i>	
Chapter 9	Neurotrophins and Their Receptors	237
	<i>Mark Bothwell</i>	
Chapter 10	Tourette's Syndrome and Pharmacotherapy	263
	<i>Pieter Joost van Wattum and James F. Leckman</i>	
Chapter 11	Neuropharmacology of Attention-Deficit/Hyperactivity Disorder	291
	<i>Paul E. A. Glaser, F. Xavier Castellanos, and Daniel S. Margulies</i>	
Chapter 12	Psychopharmacology of Autism Spectrum Disorders	319
	<i>Adriana Di Martino, Steven G. Dickstein, Alessandro Zuddas, and F. Xavier Castellanos</i>	
PART III	NEURODEGENERATIVE AND SEIZURE DISORDERS	345
Chapter 13	Stroke: Mechanisms of Excitotoxicity and Approaches for Therapy	347
	<i>Michael J. O'Neill, David Lodge, and James McCulloch</i>	
Chapter 14	Epilepsy: Mechanisms of Drug Action and Clinical Treatment	403
	<i>William H. Theodore and Michael A. Rogawski</i>	
Chapter 15	Pharmacotherapy for Traumatic Brain Injury	443
	<i>Donald G. Stein and Stuart W. Hoffman</i>	
Chapter 16	Dementia and Pharmacotherapy: Memory Drugs	461
	<i>Jerry J. Buccafusco</i>	

Chapter 17	Pharmacotherapy and Treatment of Parkinson's Disease	479
	<i>Wing Lok Au and Donald B. Calne</i>	
Chapter 18	Parkinson's Disease: Genetics and Pathogenesis	523
	<i>Claudia M. Testa</i>	
Chapter 19	Invertebrates as Powerful Genetic Models for Human Neurodegenerative Diseases	567
	<i>Richard Nass and Charles D. Nichols</i>	
PART IV	NEUROIMMUNOLOGY	589
Chapter 20	Myelin Lipids and Proteins: Structure, Function, and Roles in Neurological Disorders	591
	<i>Richard H. Quarles</i>	
Chapter 21	Pharmacology of Inflammation	621
	<i>Carmen Espejo and Roland Martin</i>	
Chapter 22	Pharmacological Treatment of Multiple Sclerosis	671
	<i>B. Mark Keegan</i>	
Chapter 23	Novel Therapies for Multiple Sclerosis	683
	<i>Martin S. Weber and Scott S. Zamvil</i>	
Chapter 24	Neuropharmacology of HIV/AIDS	693
	<i>Sidney A. Houff and Eugene O. Major</i>	
PART V	EATING AND METABOLIC DISORDERS	731
Chapter 25	Leptin: A Metabolic Perspective	733
	<i>Dawn M. Penn, Cherie R. Rooks, and Ruth B. S. Harris</i>	
Chapter 26	Ghrelin: Structural and Functional Properties	765
	<i>Birgitte Holst, Kristoffer Egerod, and Thue W. Schwartz</i>	
Chapter 27	Mechanisms Controlling Adipose Tissue Metabolism by the Sympathetic Nervous System: Anatomical and Molecular Aspects	785
	<i>Sheila Collins, Renato H. Migliorini, and Timothy J. Bartness</i>	
Chapter 28	Antiobesity Pharmacotherapy: Current Treatment Options and Future Perspectives	815
	<i>Yuguang Shi</i>

1.1 ACTION OF CURARE

Claude Bernard (1813–1878; Fig. 1.1a) recalled that, “in 1845, Monsieur Pelouze gave me a toxic substance, called curare, which had been brought to him from America” [1]^a. He injected some into a frog. The frog became paralyzed. A “physiological dissection” showed that the heart was beating, blood was flowing, and the intestines were motile. He stimulated motor nerves with a shock from an inductorium powered by a battery made of alternating zinc and copper plates charged with vinegar. In the curarized frog the muscles contracted when stimulated, but not when the motor nerve was shocked. Curare might be blocking nerve conduction. To check this, he prepared a pithed frog, ligaturing off the arterial circulation to the legs but leaving their nerves intact. When he stimulated the nerve running down the leg, the muscles contracted. Then he injected curare. The upper part of the frog’s body became flaccid and respiration stopped. When he pinched the skin on the frog’s back, the legs were pulled up, just as in a normal frog. In the curarized anterior part of the frog the sensory nerves and spinal cord obviously worked even though the motor nerves did not. Muscles throughout the preparation contracted when stimulated directly. The drug acted on motor nerves. In isolated nerve–muscle preparations the muscle contracted when it or the nerve was stimulated. When the nerve was soaked in curare solution, the muscle still responded to nerve stimulation. When the muscle was soaked in the drug, it no longer contracted when the nerve was stimulated but did contract when stimulated directly. The poison does not block most of the motor nerve; it acts somewhere after the nerve has entered the muscle.

To us Bernard’s work with curare is straightforward science. To his contemporaries it was a dazzling display of how experiments can reveal how the body works and vivid proof that a drug may target a specific site in the body [3]. According to Bernard’s student, Paul Bert, Bernard had a “love of certainty” [4]. “He discovered as others breathed.” He was aware not only of “the endless multiplicity of unknown data in physiology, but also their subordination to the general laws of matter and their obedience to experimental method.” The thesis of this chapter is that working out precisely how curare acts provided the conceptual framework for much of neuropharmacology.

Bernard found that low doses of curare paralyzed the limb muscles but did not block the contractions of the diaphragm. These animals lived and recovered when

^aTo keep the bibliography within bounds many references are to reviews rather than original papers. Information about the lives and works of Nobel Laureates come from nobelprize.org. Information about individual drugs is from [2], which has excellent historical sections.

Figure 1.1 (a) Claude Bernard. (b) Sir William Foster; relaxing during a trip to the United States. (Courtesy of the Wellcome Library, London.)

they rid themselves of the drug. Curare introduced into the stomach did not poison the animal. When the gastric juice was removed and injected, it paralyzed the subject. Hence curare was not absorbed from or destroyed by the stomach. He considered curare to be “an instrument which dissociates and analyzes the most delicate phenomena of the living mechanism” [5].

His experiments were bedeviled by using different preparations of the drug; curare is a generic term for arrow poisons from the Amazon Basin [6]. After its discovery by Europeans it was years before Alexander von Humboldt (1769–1859) found an old native who had “the impassive air and pedantic tone formerly found in the European pharmacist” and who showed him how it was done. It was a water extract of the bark from a climbing vine of the genus *Strychnos*—which took a knowing eye to identify—with the water boiled off to leave a tar-like residue. By the 1880s chemists had found that there are different alkaloids in the curare from different regions which were categorized by their packaging: pot, calabash, and tube. The latter was the most potent and its active principle is (+)-tubocurarine chloride hydrate (+ TC). All but the finer points of its structure were worked out in the 1930s (Fig. 1.2).

1.2 BERNARD'S CAREER

Bernard presented his work on curare to the French Academy of Sciences, which met weekly. The academy was founded in 1666. In 1835 it began to issue the *Comptes Rendus*, where Bernard published [7]. He also wrote books describing his major discoveries, and his popular article on curare thrilled readers with his vivid description of the curarized animal: “All though the ages poetic fiction has sought to awaken our pity by representing living creatures locked in inanimate bodies” [8]. His early discoveries established his reputation and in 1854 he was appointed to a new chair in general physiology at the Sorbonne. It was a time when many universities were building up science. In 1858 he moved to the chair of medicine at the Collège de

Figure 1.2 Some of the wealth of plant products that were starting points in the development of neuropharmacology.

France. The Emperor Napoleon III, after a lengthy talk at a social gathering, had a laboratory built for him in 1864. He joined the “40 immortals” in the Académie Française in 1868, and the next year was appointed to a seat in the Sénat.

He was born in the village of St. Julian to a family of Burgundian vintners [9]. His father was a poor school master. As a lad he wanted to be a writer. At 19 he came to Paris “with almost no paraphernalia except a tragedy which had never been acted and a farce-comedy which had some success at a small theater in Lyons” [4]. He carried an introduction to a prominent critic, who read his work and advised him to take up a profession and write on the side. In medical school he was a mediocre student; in the final examination he placed 26 out of 29. He had a talent for doing beautiful dissections, which is why the physiologist François Magendie (1783–1855) asked him to assist in preparing facial nerves for experiments. Magendie had demonstrated the separation of motor and sensory nerves in the roots of the spinal cord and in 1821 had founded the first physiological journal: the *Journal de Physiologie Expérimentale*. The leading French pharmacists were isolating potential drugs from plants; Magendie often tested their products. Had he tested curare it would probably have satisfied him to observe the paralysis. Once in a laboratory all of Bernard’s hitherto hidden talents flashed into view. He influenced many by his teaching. The scientific content of Bernard’s lectures was high, but organization might collapse. If his line of thought “escaped him, he followed it without rebellion, leaving his speech drooping, his lecture in confusion, while he listened softly to what it said to him” [4].

His personal life was deeply troubled. He married for money. His wife wanted him to practice medicine—as Magendie always did—so they would have a splendid

income. Bernard had time only for science. Even more troubling she was an ardent opponent of vivisection, writing her husband long letters denouncing his practices and enlisting their two daughters in her cause. When he fell ill at the end of 1877, he diagnosed his own doom [10]. Experiments, including some with curare, were unfinished: “What a pity, it would have been good to finish it” [4]. He was the first scientist given a state funeral in France.

The story of the action of curare I have presented so far is, as any working scientist will appreciate, far too simplified. There was an appreciable literature before Bernard, primarily showing the deadly effects of the poison were due to suffocation; artificial respiration kept curarized animals alive [6]. After Bernard published his results, Alfred Vulpian (1826–1887) proposed that the target for curare is the motor end plate of the muscle fibers, which had just been discovered [11, 12]. One of Bernard’s students then described in detail the motor end plates in lizard muscles and thought that he could distinguish those that had been exposed to strong curare solutions from normal [13].

1.3 SCIENTISTS, PATRONS, AND MONEY

There is a fundamental difference between the histories of science and scientists and those of art and artists or politics and politicians. Without Michelangelo the painting on the ceiling of the Sistine Chapel would be completely different; without Claude Bernard we would still know where curare acts—and all of his other discoveries as well. Scientists are placing pieces in a jigsaw puzzle that is predetermined by the laws of nature and evolutionary history—physical and organic. But this does not mean that great scientists are less important than great artists, musicians, or politicians. Bernard and his contemporary Louis Pasteur (1822–1895) led by sweeping the cobwebs of vitalism out of French biology. Their fame stimulated public interest in and support for science. Thinking of public support reminds us of another aspect of history that is too often slighted. Michelangelo and his assistants painted the ceiling of the Sistine Chapel, but only because of Pope Julius II. He compelled Michelangelo to move to Rome to repaint the ceiling and financed the project from the vast resources of the Catholic Church. Paying for the salaries, supplies, laboratories, and the like is even more important in science. Hence, as we go along, I will call attention to some patrons of science and to some of the sources of funds for paying for research.

1.4 A CHANGING WORLD

In Bernard’s lifetime Europe changed almost beyond comprehension. He came to a Paris of medieval streets. When he died it was crisscrossed by wide boulevards lined with stone-faced apartments and shops with large glass windows under wrought-iron balconies and shining at night in the light of gas lamps. Over the nineteenth century the population of Europe increased almost fourfold, despite millions emigrating for opportunities elsewhere. The world population had started growing rapidly at the beginning of the eighteenth century (Fig. 1.3a) [14]. A major reason for such rapid growth was improvements in agricultural practice. With better nutrition people lived longer. With more people who took in more energy for work there was an explosive

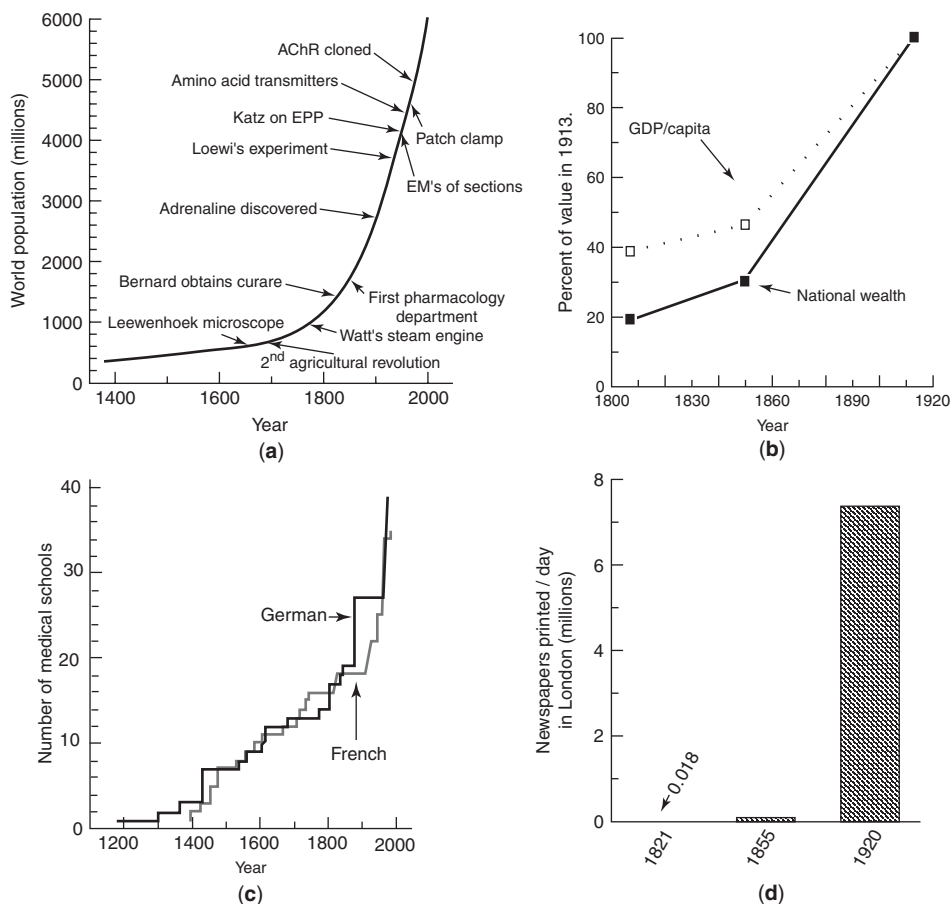

Figure 1.3 Some of the changes in the modern era. (a) World population. Note the change in rate at about 1700. To my mind the growth of science follows a similar curve. The estimated population at year 0 is about 200 million. (Data from Robert W. Fogel, Nobel Laureate in Economics, 1993) [14]. (b) The rise in the GDP in the Netherlands and the increase in national wealth. The Netherlands was chosen for the example because of the reliability of the data from the Groningen Growth and Development Centre [www.ggde.net]. (c) The numbers of still-existing medical schools in Germany and France as a function of time. (d) The number of newspapers printed on a weekday in London. The bar for 1821 is too small to be seen, so the figure is indicated above it [15].

expansion of industry. The energy of the workers was then supplemented by energy from fossil fuels trapped as steam. Over the nineteenth century the gross domestic product (GDP) per capita more than doubled (Fig. 1.3b). The increases in wealth and population led to the founding of universities and medical schools (Fig. 1.3c). The number of scientists was rapidly expanding. In France, the medieval universities had been torn asunder by the revolution. They were reformed and supplemented by the establishment of new schools specifically oriented to training in the professions. They were all supervised by the Université de Francé.

There was also an explosion in the availability of information. Steam presses slashed the cost of printing. There was an enormous increase in newspaper

circulation (Fig. 1.3d) [15]. Therefore many citizens knew of Bernard's work on curare and of advances in medical care, like the development of anesthesia—positive reinforcements for supporting science.

1.5 GERMAN-SPEAKING UNIVERSITIES

A political map of the Germany of 1800 shows a hodgepodge of kingdoms, principalities, bishoprics, and free cities united only by language and culture. During the Reformation the medieval universities had been taken over by the “states” [16, 17]. As population and wealth increased, so did support for the universities, and new ones were founded. Professors were expected to enlarge knowledge as well as to teach, and they decided what would be taught and what would be investigated. The goals for the universities had been enunciated by the first dean of the faculty of philosophy in Berlin, Johann Gottlieb Fichte (1762–1814), in a series of “Addresses to the German Nation” delivered in 1808–1809. Universities were built on three maxims: the freedom of the individual, of research, and of the nation. University life then was much like today; Fichte was the first rector in Berlin but soon had a conflict with the faculty and resigned.

The universities were open to all who had graduated from a classical high school, or “Gymnasium”. They had been started in 1815 and spread rapidly, and the States paid for education. There was no tuition, but some of the university lecture courses charged fees. The top 10% or so of the students worked for a doctorate, which supposedly attested to competence to work as a scholar in the field, though it was recognized that in medicine this ideal was seldom achieved.

A professorial chair was worth fighting for; as Max Weber (1864–1920) famously wrote, “many are called but few chosen”. There was a well-recognized pecking order among the universities, and professors competed to move up the ladder. The first pharmacology department was founded at the German-speaking University of Dorpat in Estonia in 1847 [18]. The first pharmacology department in Germany opened in 1849, and they spread rapidly throughout the country, partly because they were so useful to the booming German Chemical Cartel.

In 1870 Napoleon III declared war on Prussia. He found himself fighting all of the German states. After their victory they formed the German empire, and many of the states allocated part of their share of the enormous reparations extracted from the French to strengthen their universities. A major beneficiary was Strasbourg, in Alsace, which was taken over by Prussia. Oswald Schmiedeberg (1838–1921), who had studied at Dorpat, was appointed professor of pharmacology. He discovered that vagal stimulation slows the heart and became known as the “father of pharmacology” because 40 of his students obtained chairs. The professor of pathology was Bernhard Naunyn (1839–1925). In 1873 the two founded the *Archiv für Experimentelle Pathologie und Pharmakologie*.

1.6 MICHAEL FOSTER

Synaptic neuropharmacology would flourish in Great Britain—astonishing to anyone who had surveyed the situation there in 1850. Oxford and Cambridge were

assemblies of private corporate colleges, with their medieval, ecclesiastical roots largely unpruned [19]. Only members of the Church of England could be awarded degrees. The fellows were forbidden to marry. Pushed by German competition, they were transformed into scientific powerhouses by the leadership of men like Michael Foster (1836–1907; later Sir Michael; Fig 1.1b) [20]. Bernard was his inspiration; Foster wrote: “he has been to me as a father in our common science” [9].

Foster studied medicine at University College London (UCL)—known to its detractors as “the godless institution on Gower Street”—because he was a non-conformist. He spent a year in Paris but never “saw Bernard’s face.” After six years in medical practice he became an instructor at UCL and then Fullerian professor at the Royal Institution in London. He worked on the snail heart, trying unsuccessfully to determine whether beating is myogenic or neurogenic. The choice of preparation shows his affinity for Darwin’s ideas—evolution became bedrock in British physiology. He moved to Cambridge—without a university appointment—to a teaching position at Trinity College; this sidestepped the religious and marriage problems. Foster’s remit was to develop biological science. They gave him £400—roughly \$80,000 in the year 2000—for equipment, a room loaned by the university, and an assistant, Henry Newell Martin (1848–1893). A year after Foster’s arrival the religious tests at Cambridge and Oxford were abolished when Parliament, after years of acrimonious debate and reports by royal commissions, amended the charters to remove the religious requirement and to permit fellows to marry.

Foster invited interested students to see the body at work: muscles contracted, nerves conducted, exocrine glands secreted. Many found this thrilling and yearned to work on living things with their own hands. He persuaded the best to become botanists, histologists, embryologists, or physiologists—wherever there was a need. “He was a discoverer of men rather than facts” [21]. He sold research, “in this way only lies salvation”. He also provided scientists for other institutions. In 1876 he arranged for Martin to move to Johns Hopkins, which was just opening the first German-style university in the United States.

In 1878 Cambridge constructed a Biological School building, even though legally Foster and many of his staff were not part of the university. Finally in 1883, following a report by another royal commission and an act of Parliament, Foster was appointed professor of physiology. His *Textbook of Physiology*, first published in 1877, went through many editions in many languages, almost surely becoming the most widely used physiology textbook of the time [22]. It is filled with detailed descriptions of experiments and illustrations of the raw data. The 1893 edition concludes that it is not known how the motor nerve excites the muscle. Curare is not mentioned. There is no overview of the autonomic nervous system. Atropine, a product of the deadly nightshade, *Atropa belladonna*, blocks the action of the vagus on the heart and is said to act either on the muscle itself or on the “ultimate nerve endings” (Fig. 1.2). Atropine also blocks salivary and sweat gland secretions in response to nerve impulses and dilates the pupil. Muscarine is an alkaloid from the poisonous mushroom *Amanita muscaria*. Schmiedeberg was the first to isolate it and then he showed that it mimics the action of the vagus (Fig. 1.2). Drugs were known that acted on transmission between nerve and effector, but there was no integrating overview whatsoever.

In England the physiologists also taught histology. This was one of their strengths, since they all could do their own microanatomy. As his group grew, Foster turned the

teaching over to his protégés, a step that was welcomed by the students. Charles Scott Sherrington (later Sir Charles, 1857–1952, Nobel Laureate 1932), a student in the 1880s, found Foster “an appalling lecturer” and “never saw him do any demonstration” [21]. Often the young are not kind to their elders. Pharmacology came to Cambridge in 1899 in the form of Walter Ernest Dixon (1871–1931), who was appointed as an assistant to the Downing professor of medicine [23]. He had trained at St. Thomas’s Hospital London, where he worked on the addictive properties of cannabis and mescaline. “Pharmacological teaching in England, before Dixon began, was an unappetizing mixture of half obsolete *material medica* and empirical therapeutics. In Dixon’s hands it became a lively adventure in experimental science” [24]. The first pharmacology department in Britain opened in 1905.

Foster persuaded a rich student, Albert George Dew-Smith (1848–1903), to set up a company to manufacture apparatus. After a few years the firm was reorganized with Horace Darwin (1851–1928), Charles’s fifth son, as a partner and designer; the joint enterprise became the Cambridge Instrument Company [25]. There was a strong antivivisection movement in Britain, and in 1876 a law was enacted regulating the use of experimental animals. Concerned about how the law would operate, Foster organized the Physiological Society. It met periodically to discuss the workings of the law, but some scientific talk slipped in. Soon there were formal scientific sessions, which included the demonstrations Foster loved. Dew-Smith provided the financial support for starting the *Journal of Physiology*, which from the beginning had some foreign editors. Then Foster initiated international physiological congresses. The first was held in Basel in 1889. He served as secretary of the Royal Society from 1881 to 1903. His major achievement there was to persuade the fellows that it was appropriate for the society to provide scientific advice to the government.

1.7 GASKELL AND LANGLEY

Walter Holbrook Gaskell (1847–1914) followed his teacher Foster by working on the heart beat [26]. After years of careful work he showed that there are no nerve cells in the base of the ventricle of the turtle heart but that it could beat for at least 30 h when isolated—the beat is myogenic. Gaskell then worked on the structure of the involuntary nervous system, which he summarized in a book [27]. From there he turned to work on the evolutionary origin of the vertebrates. He inspired physiology students; “he spoke on controversial points with a half-suppressed enthusiasm which was eminently infectious” [24].

John Newport Langley’s (1852–1925; Fig. 1.4a) first paper began “Dr. Foster, having received from Dr. Ringer...a small quantity of the alcoholic extract of *jaborandi*, placed the drug in my hands and requested me to observe its physiological action” [28]. It was an extract of *Pilocarpus jaborandi*, a medicinal plant from South America, which contained the alkaloid pilocarpine. Langley found that pilocarpine slowed the frog heart or the beating of its isolated parts. Atropine antagonized pilocarpine. The plant was chewed to induce salivation. This led Langley to a 15-year study of salivary glands [29].

In 1890 he started working with the alkaloid nicotine, from the tobacco plant, *Nicotiana tabacum* (Fig. 1.2) [30]. When injected it produced a bewildering variety of

Figure 1.4 (a) John Newport Langley. (b) Sir Henry Wellcome. (Courtesy of the Wellcome Library, London.)

effects. He pinpointed sites of action by exposing a tissue, blotting it with a paper, and then—using a fine brush of sable hair—placing a $0.05\ \mu\text{L}$ drop of nicotine solution on its surface. He found that nicotine acted on autonomic ganglia, first exciting and then blocking, but had no effect on the pre- or postganglionic axons. Curare antagonized the stimulation by nicotine; atropine did not.

Working on frog and chicken skeletal muscles, he found that the results depended on the muscle chosen for study [31]. With a muscle like the frog sartorius, where there are seldom more than two end plates on a fiber, low concentrations of nicotine placed near the nerve endings elicited a brief burst of twitches. These are called twitch fibers. Following the contractions there was a block in neuromuscular transmission. The excitatory effect was blocked by curare at lower doses than required at the ganglia. Elsewhere on the twitch fibers there was no response unless the nicotine concentration was increased by orders of magnitude. Other muscles, like the frog rectus abdominis, are made up of fibers that are sensitive to nicotine almost all along their lengths, which became known as tonic fibers. Langley did not know that tonic fibers have end plates all along their length. The tonic fibers give a sustained contraction when nicotine is applied. Other muscles contain a mixture of the two types of fibers, so their response to nicotine was bewildering indeed. It did not faze Langley, who preached “get facts, then theory will take care of itself” [20]. Muscle denervated 100 days earlier still responded to nicotine. His view on the mechanism was based on Paul Ehrlich’s (1854–1915; Nobel Laureate 1908) hypothesis that protoplasm is one giant molecule and that drugs act on its side chains. Hence Langley concluded that the drug acts “directly on the muscle. In the muscle there are two substances to take into account, the sarcoplasm and the differentiated contractile substance. ...I take it that the contractile molecule has a number of ‘receptive’ or side-chain radicals, and that nicotine, by combining with one of these causes tonic contraction, and by combining with another, causes twitching, and that the latter is a much less stable part of the molecule” [31].

He summarized the anatomy and physiology of the autonomic nervous system in a book in which he described the evidence for two components, which he named sympathetic and parasympathetic [32]. The effects of parasympathetic stimulation are mimicked by muscarine, pilocarpine, and choline and blocked by atropine. He called these cholinophil. Most effects of sympathetic stimulation are mimicked by adrenaline (see below) and were called adrenophil. Sympathetic stimulation causes sweat glands to secrete but adrenaline does not. Sweating is blocked by atropine and stimulated by choline and the rest. In his view, there were cholinophil and adrenophil receptors, but they could be either excitatory or inhibitory depending on the chemical changes in the tissue when the drug combined with the receptor.

Langley edited the *Journal of Physiology* for 30 years. Edit is too light a word. Almost invariably he would heavily correct papers and sometimes he would rewrite them completely. When Foster left, Langley became professor of physiology. He had much to do. The staff was excellent, the facilities deplorable. Three investigators shared a former coal cellar. Finally in 1914 a splendid new building was opened paid for by a London company, the Drapers'. Companies such as this are descendents of the medieval guilds which are now given over to good fellowship and good works. His research was supported by grants from the Royal Society and the British Medical Association. He inspired students by how relentlessly he worked at a problem and with his success in putting together the puzzle, not by warmth of personality. Langley was a brilliant figure-skater. One student thought this caught his essence: "brilliant technique on an icy background" [29].

1.8 THE SYNAPSE

Langley's papers at the beginning of the twentieth century vividly show the uncertainties about the pathway from nerves to muscles or glands. Was there cytoplasmic continuity? Were cells surrounded by membranes, and if so was there a gap between the nerve and the structure it innervated? The best microscopes revealed no membrane and no gap. Most electrophysiologists were convinced that the unseen membranes existed and thought that nerve impulses were transmitted by momentary changes in their properties [33]. In 1897 Sherrington proposed that the attributes of reflexes are due to the properties of the junctions between individual nerve cells, at structures he called synapses [34]. He pictured the synapse as a gap between the neurons bounded by the apposing membranes of the two cells. Synapses accounted for one-way conduction in the reflex arc and for the delay added onto the passage of the nerve impulses traversing the arc. However, synaptic delay is extremely short and transmission can be repeated at short intervals. Too fast, they argued, for a chemical reaction between a hypothetical transmitter and receptor, let alone further chemical reactions to produce an effect. Transmission must be electrical, just as it is down the nerve axon.

Camillo Golgi (1843–1926) and Santiago Ramón y Cajal (1852–1934) shared the Nobel Prize for Physiology or Medicine in 1906 for their work on the structure of neurons. They developed treatments that stained randomly selected neurons in their entirety: cell bodies, axons, and dendrites. Cajal argued that therefore there is no continuity between the cytoplasm of the individual neurons. As he said in his lecture, "it must be admitted that the nerve currents are transmitted from one

element to another as a consequence of a sort of induction or influence from a distance.” Golgi was more cautious, suggesting that at least some parts of the brain were made of an extensive reticulum rather than individual cells.

The Nobel Prizes, first awarded in 1901, rewarded outstanding investigators and publicized scientific progress. Citizens were elated when a fellow countryman won a Nobel Prize and were willing to see more of their taxes go toward science so they might do better in the international competition.

Ross Harrison (1870–1959) did not receive the Nobel Prize voted for him because none were awarded in 1917 due to the “Great War” [35]. Harrison placed bits of frog spinal cord in a drop of lymph on a sterile cover slip sealed over a hollow slide. For weeks he watched axons grow out from a ganglion cell, sometimes at a rate of 50 $\mu\text{m}/\text{h}$. The axons grew out to muscle fibers in the culture, which then contracted spontaneously [36]. There must be a synapse between the motor nerve and muscle.

1.9 DALE AND LOEWI

Among the Cambridge students inspired by Langley and Gaskell was Henry Hallett Dale (1875–1968; later Sir Henry) [37]. He did well in physiology and was awarded a research fellowship which enabled him to spend two years preparing a thesis as a candidate for a fellowship at Trinity College. Under Langley’s direction Dale did a morphological census of the various classes of fibers in a mixed nerve. It was dull work and did not get him the fellowship. Disappointed, he moved to London for the clinical part of the medical course. The clinicians “felt it obligatory to speak with a kind of oracular authority” with little scientific basis [37]. He won a fellowship to work in the Physiology Department at UCL. The fellowship was endowed by the writer George Eliot (1819–1880) in memory of her long-time companion George Henry Lewes (1817–1878). The professor was Ernst Henry Starling (1866–1927), who was then collaborating with his brother-in-law William Maddock Bayliss (1860–1924; later Sir William). They had just discovered the first hormone, secretin. Dale was asked to study the effects of large doses of secretin on the histology of the pancreas, work which he did not enjoy.

In 1902 Otto Loewi (1873–1961) came over from Germany for a few months to meet British scientists and to improve his English [38]. Dale tried to help with words and phrasing, but soon learned that his enthusiastic friend was not interested: “No. I have no time to learn English correctly; I wish to speak it fast.” The British were charmed with his fractured outpourings: “some of his achievements in that line have had a legendary survival, still being known... 60 years later.” Loewi also spent several weeks with Langley in Cambridge. At that time Loewi was an assistant in the Department of Pharmacology at Magdeburg, where the professor was Hans Horst Meyer (1853–1939). Meyer had shown that the deadly tetanus toxin is taken up in nerve endings and transported up the axons into the central nervous system (CNS), where it acts. Then he turned to kidney pharmacology. Loewi liked working with drugs, which he defined as “chemicals which when injected into an animal or applied to a tissue result in the publication of a scientific paper.”

Loewi had attended the University of Strasbourg where, at the insistence of his parents, he enrolled in medicine. Initially he “played hooky” from medicine, favoring lectures on architecture and philosophy which he loved [39]. One day, to obtain a

required signature, he went to Naunyn's class, hoping to get the signature before the lecture began. He was late, so he stood in the doorway waiting for it to be done. He was fascinated by the lecture, so he came again and became an enthusiastic student of medical science. Schmiedeberg directed his doctoral thesis. Loewi was surprised by the crowding and poor equipment in the British laboratories. In the German universities there was no fretting about funds or writing of grant proposals. The governments paid the bills but gave them "far-reaching autonomy," accepting "the universities proposals and paying the endowments and debts of the departments. ...If the debts were excessive the department got a warning—and a little later the payment" [39].

After Loewi returned home, Dale visited Germany: first to Magdeburg and then to Frankfurt-am-Main, where he spent four months working in Ehrlich's department. There "I had no results of my own worthy to record" [37]. Back in London, he had a job at UCL, at £150 per year, less than his fellowship had paid, so he was receptive when approached by Henry S. Wellcome (1853–1936; later Sir Henry; Fig. 1.4b), the proprietor of the huge pharmaceutical company Burroughs Wellcome.

1.10 HENRY WELLCOME

Wellcome had grown up in a farming community in Minnesota, where as a lad he worked in his uncle's drug store [40]. The office above was occupied by William James Mayo (1861–1939), who with his brother later established the Mayo Clinic. He encouraged young Wellcome to attend the Philadelphia College of Pharmacy, considered the best in the country. There he met Silas Burroughs (1846–1895). After graduation Wellcome worked in Peru and Ecuador, obtaining specimens of plants the inhabitants used medicinally. Burroughs had moved to London. He invited Wellcome to join him there in a company which would manufacture the new compressed medicinal pills. The compression process had been developed by an English artist for making better lead pencils. In Britain most physicians were still rolling their own pills. The Burroughs Wellcome Company made the pills and advertised them vigorously in professional journals, and by the time Wellcome was 30 the company had facilities around the world and he was very rich. The partners fought bitterly and were dissolving their partnership when Burroughs died of pneumonia. Wellcome became sole proprietor.

Wellcome understood that only research could expand the pitifully short list of useful drugs, so he set up The Wellcome Research Laboratories in Physiology in a southern suburb of London. They started by producing diphtheria antitoxin in horses. The antitoxin had been developed at the Pasteur Institute, but Wellcome was the first quantity producer. For its first 10 years the laboratory did no research.

1.11 ERGOT AND ADRENALINE

Wellcome wanted some real research done at his laboratory so he offered Dale £400 per year (equivalent to about \$60,000 in 2000). Dale's advisers all warned him that "I would be selling my scientific birthright for a mess of commercial potage" [24]. Still he would have "a marrying income" and be free from teaching, so he accepted, with the

proviso that his salary would be raised to £600 in two annual increments. Wellcome suggested that “when convenient, he would be glad to have me make some investigations on the pharmacology of ergot” [37]. Parke Davis & Co advertised that its ergot preparation was biologically standardized and Wellcome was eager to compete. Ergotamine is produced by a fungus, *Claviceps purpurea*, which infests rye and other grains (Fig. 1.2). It causes gangrene of the extremities, along with agonizing burning pain. Its toxicity had been known to the Assyrians, and it had been used by midwives to bring on delivery when labor was delayed well before it was adopted by physicians.

Wellcome was also interested in marketing adrenaline, which had been discovered in 1895 when Oliver and Schäfer injected an adrenal extract and recorded an increase in blood pressure that almost shot the mercury out of their manometer. Dale knew a great deal about adrenaline, because a close friend from Cambridge, Thomas Renton Elliott (1877–1961), had worked on it [41]. Following earlier work by Langley and others, Elliott showed: “In all vertebrates the reaction of any plain [smooth] muscle to adrenalin is of a similar character to that following excitation of the sympathetic (thoracico-lumbar) visceral nerves supplying that muscle. The change may be either contraction or relaxation” [42]. Denervated smooth muscles that had been innervated by the sympathetic system still respond to adrenaline and their sensitivity is enhanced. The last sentence of Elliott’s abstract when he presented this work to the Physiological Society was: “Adrenaline might then be the chemical stimulant liberated on each occasion when the impulse arrives at the periphery” [43]. This audacious idea did not make it into his paper, probably because Langley did not like it. When Elliott finished his work with adrenaline, he did not receive a fellowship so he entered medical school in London.

The link between ergot and adrenaline was discovered by Dale. One day he was measuring the effects of graded doses of ergot extract on the blood pressure of a spinal cat. When the tests were almost finished a sample of dried adrenals from the Burroughs Wellcome factory was delivered. He was to determine its adrenaline content. No need to waste the cat. When Dale injected the adrenal extract, the blood pressure fell, “and with the confidence of inexperience I condemned the sample without hesitation.” The same result a week later made him realize that he had made a “really shocking howler.” Ergot blocked excitatory effects of adrenaline without touching its inhibitory actions. It also blocked excitatory effects of sympathetic nerve stimulation. It did not block inhibitory effects of adrenaline or of nerve stimulation. Shortly thereafter, Dale was named the director of the laboratory.

He and George Barger (1878–1939), a chemist at the Institute, then studied more than 50 amines for what they christened their “sympathomimetic” actions—another term that has become part of the language. The closer the resemblance to adrenaline, the more potent the amine. Noradrenaline is a stronger exciter and weaker inhibitor than adrenaline. At the time noradrenaline was not known to occur in the body, so they passed over the implications.

1.12 HISTAMINE

One of the amines they worked with was histamine, which they had found in their ergot extracts and later showed was produced by bacterial action on histidine. It stimulates many smooth muscles but when injected causes a dramatic fall in blood

pressure: Its effects are much like anaphylactic shock. A few years later colleagues at the Institute showed that histamine is in the body. Working on the isolated guinea pig uterus one day, comparing the stimulation of contraction caused by histamine and by horse serum, Dale was startled to find that the serum was working at unexpectedly low concentrations. He inquired about the previous use of the guinea pig and learned that it had been injected with small amounts of horse serum in an assay of antitoxins. He picked up the clue and showed that the previous exposure to the serum *in vivo* sensitized the smooth muscle to subsequent challenges with serum: the basis for anaphylactic shock.

1.13 ACETYLCHOLINE

Working one day with a crude extract made from ergot on the spinal cat, Dale was startled to see the blood pressure fall to zero. He thought he must have clumsily injected enough air to stop the heart pumping: “And then, as I was hanging up my blouse, assuming that my mornings work was done, I caught sight of the recording drum out of the corner of my eye, and saw that the manometer float was rapidly returning to the level of the blood pressure record before the injection” [43a]. A second injection also temporarily stopped the heart. He injected atropine. Now the extract had no effect. He told his chemistry colleague, Arthur James Ewins (1882–1957), that the extract contained a substance that acted like muscarine. Ewins promptly isolated the base as a platinum salt, but determining its structure with a tiny sample was a formidable task. “That evening, in fact as I was getting into bed,” Dale remembered a report he had read eight years before that low concentrations of acetylcholine (ACh) slowed the heart. The next morning he asked Ewins “to get to work and make me some acetylcholine as soon as possible... Before many hours had passed we knew beyond doubt that the active principle we had found in the ergot salt was, indeed, physiologically indistinguishable from acetylcholine” [43a]. With this hint, Ewins identified his platinum salt as that of ACh.

Soon they showed that ACh acted like muscarine on heart, smooth muscle, and glands. And both were antagonized by atropine. Like nicotine it stimulated secretion from the adrenal medulla, where the ACh action was blocked by paralyzing doses of nicotine. They coined the terms *nicotinic* and *muscarinic* to describe the two actions of ACh. They were tantalizingly close to the answer: the result “gives plenty of scope for speculation.” But they did not think of an experiment to make the leap.

1.14 NATIONAL INSTITUTE FOR MEDICAL RESEARCH

Meanwhile Dale had moved. In 1908 the Liberal government in Britain passed a budget in the Commons that initiated unprecedented social reforms, a vast program modeled on what the Germans had achieved in Bismarck’s time. They established old-age pensions, workman’s compensation, an 8-h workday for miners, medical inspection of children, and unemployment insurance. The budget was only implemented after a prolonged fight with the House of Lords and two general elections. In 1912 the emboldened liberals included national health insurance in the budget. A small fraction of the premiums— “one penny per head per annum per insured

person”—was set aside for medical research. The government established the Medical Research Council (MRC) to spend the funds.

Dale was appointed director of the Department of Biochemistry and Pharmacology at the National Institute for Medical Research (NIMR) in London, which was established by the MRC. Dale was delighted to leave Wellcome, who too often made promises that were not implemented because he headed off on an expedition—he was an ardent archeologist and collector—before leaving instructions. The development of the NIMR was sidelined by the outbreak of World War I. Dale worked on antiseptics, antiamebic dysentery agents, and “wound shock,” concluding that treatment should be by “the addition by transfusion to the circulating blood of a fluid...—blood or plasma” [43a]. In 1920 the NMIR finally moved into quarters in Hampstead. Dale and his family were already living in a small manor house on the site rented from the MRC. Dale became its director in 1928.

1.15 LOEWI'S EXPERIMENT

The decisive experiments on synaptic transmitters were started on the Monday after Easter in 1920 at 3:30 in the Pharmacological Laboratory of the University of Graz Austria; Loewi had become professor there in 1909. Here is the experiment in his words [39]. (Note that a Straub canula is a glass tube that can be slipped though the stump of the aorta into the single ventricle of the frog's heart.) “The hearts of two frogs were isolated, the first with its nerves, the second without. Both hearts were attached to a Straub canula filled with a little Ringer solution. The vagus nerve of the first heart was stimulated for a few minutes. Then the Ringer solution that had been in the first heart was transferred to the second heart [Fig. 1.5a]. It slowed and its beats diminished just as if the vagus had been stimulated. Similarly when the accelerator nerve was stimulated and the Ringer from this period transferred, the second heart speeded up and its beats increased.” How clever to use frog hearts both for releasing the chemicals and performing the bioassays.

He called the substance released by vagal stimulation *vagusstoff*. It disappears rapidly if left in the ventricle and its effect on the second heart is blocked by atropine. They tested pilocarpine, muscarine, choline, and ACh by placing solutions in a heart for a time and then seeing whether the solutions had lost their potency when transferred to a second heart. Only ACh did. They then showed that hearts contained an esterase that broke down ACh. The esterase was inhibited by low concentrations of physostigmine, an alkaloid from the seeds of *Physostigma venenosum* from West Africa. It had been isolated in 1864 and used in the treatment of glaucoma since 1877. Loewi and his group showed that physostigmine inhibits what became known as acetylcholinesterase (AChE). Hence, when the effects of nerve stimulation on an organ were enhanced by physostigmine, it was likely that ACh was being released.

Years passed before Loewi's experiment was generally accepted as reproducible. It is not as easy as it sounds. Loewi was lucky because the winter frogs he started with had low levels of AChE; frogs are seasonal animals. All of the experiments he reported were done in February and March [44]. Usually AChE must be inhibited for the experiment to work, so there were many failures around the world. He submitted

Figure 1.5 Great discoverers. (a) The first published record of the Loewi frog heart experiment. At the arrows the fluid in the heart was replaced with Ringer withdrawn from a heart whose vagus had been stimulated for 15 min. (b) Otto Loewi. (c) Henry Dale. ([b,c] copyright © The Nobel Foundation.] (d) Shosaku Numa.

his paper on 20 March, 1921, almost a year after the initial experiment, presenting results from 14 experiments on frogs and 4 on toads. There must have been many failures during the summer. Finally in 1926 he was invited to supervise a demonstration at the International Congress of Physiology in Stockholm. Happily—unlike so many demonstrations—it worked 16 times on the same hearts. He was required to stand away from the apparatus, because some claimed that he dispensed ACh from under his fingernails.

The experiment of stimulating the sympathetic supply to the heart and transferring the excitation in the Ringer solution was easier to reproduce, because the released transmitter is not dealt with rapidly. The effect of the excitatory chemical was blocked by ergotamine, which also antagonizes adrenaline. The potency of the transferred Ringer was increased by doses of cocaine that by themselves were ineffectual; cocaine was known to potentiate adrenaline. The material in the Ringer had the characteristics of adrenaline. Exceptionally frog sympathetic postganglionic nerve fibers release adrenaline rather than noradrenaline.

A question Loewi delighted in chewing over was how he had the idea for his experiment in the first place, as he described it: “The night before Easter Sunday... I awoke, turned on the light, and jotted down a few notes on a tiny slip of thin paper. I fell asleep again. It occurred to me at six o'clock in the morning that during the night I had written something most important, but I was unable to decipher the scrawl. The next night, at three o'clock, the idea returned. I got up and immediately went to the laboratory.” [39]. It may have grated on his competitors that this was his first major venture into neuropharmacology. His previous work had been on nutrition, kidney pharmacology, and the effects of digitalis on the heart.

1.16 FELDBERG

Adolph Hitler (1889–1945) became the chancellor of Germany early in 1933. The Achilles' heel in the German university system was that professors were civil servants. Every Jew or person of Jewish ancestry teaching in a German university was fired. Wilhelm Sigmund Feldberg (1900–1993) was told by the professor of pharmacology in Berlin to leave immediately and never to come back [45]. Hundreds of others had similar dismissals. A few weeks later Feldberg met with a representative of the Carnegie Foundation who had a list of opportunities abroad for displaced German scholars. Regretfully, none fit Feldberg. Feldberg mentioned that if an opening surfaced he felt sure Sir Henry Dale would recommend him. This jogged the representative's memory. Searching his notes he saw that that Dale had told him that there was a place for Feldberg at the NIMR [46].

Feldberg had spent two years in England, first with Langley and then with Dale. Now he returned with a wonderful present: an ultra sensitive bioassay for ACh measuring the contractions of the physostigmine-treated dorsal body wall muscle of the leech. It is so sensitive that they could take the venous effluent from a mammalian tissue in a physostigmine-treated animal, cool it, and let it flow over the leech muscle, which contracted if ACh had been released. Feldberg and co-workers in Berlin had just shown that ACh is released in the adrenal medulla when the sympathetic preganglionic nerve is stimulated.

Dale had seldom come to the laboratory after he had become director—now he was there every free moment. He had assembled a formidable group of co-workers. John Henry Gaddum (1900–1965) had turned from medicine to pharmacology when a girl at a ball told him of an opening in Dale's laboratory [46, 47]. George Lindor Brown (1903–1971) was an Oxford-trained electrophysiologist recruited to expand the available techniques [48]. He had finished constructing his electronics and was ready to go. Soon they were joined by Marthe Louise Vogt (1903–2002), a skilled microdissector who left Germany voluntarily because she so detested the Nazis.

There was a stream of discoveries. The cat superior cervical ganglion released ACh when the preganglionic nerve was stimulated. The amount that could be released was larger than the initial ACh content, so ACh is synthesized in the ganglion. So much ACh was released that the reinjection of outflow stimulated the postganglionic fibers—therefore the ACh released surely stimulated them also. Some postganglionic sympathetic fibers, like those innervating sweat glands, release ACh. Dale coined the terms *adrenergic* and *cholinergic*.

Stimulation of the motor axons liberated ACh at skeletal muscles. When the muscle was denervated, vigorous contraction elicited by direct stimulation did not release ACh. ACh was still released when contraction was blocked with +TC. Frustratingly they could not get a muscle to contract when ACh was injected into its arterial circulation. Reasoning that the ACh reaching the tiny end-plate region would be dilute: "We attempted a nearer approach to these supposed conditions of its natural release, by a method which enabled us, after a brief interruption of the arterial blood supply, to inject a small dose of acetylcholine, in a small volume of saline solution, directly and rapidly into the empty blood vessels of the muscle. The responses which we thus obtained were of an entirely different kind from any which had previously been recorded. A dose of about 2 gamma of acetylcholine, thus injected at close range into the vessels of a cat's gastrocnemius, produced a

Figure 1.6 (a) Sir John Eccles. (b) Sir Bernard Katz (copyright © The Nobel Foundation.)

contraction with a maximal tension equal to that of the twitch produced by a maximal motor nerve volley, and of a rapidity but little less than that of the motor nerve twitch.” Vogt did the difficult dissections. Brown showed that the close injection elicited a short burst of action potentials in the muscle fibers. ACh was still released when contraction was blocked with +TC. Twenty-four papers and abstracts on ACh from Dale’s laboratories were published from 1934 to 1936. Feldberg was an author on all of them, because he did the assays.

Their results were presented at meetings of the Physiological Society. Not everybody liked them. The criticism was led by John Carew Eccles (1903–1997; later Sir John; Fig. 1.6a), a dynamic Australian who was always primed for the attack [49]. After graduating in Medicine from Melbourne, he had come to Oxford as a Rhodes Scholar in 1925. His sport—one of the selection criteria for a Rhodes—was pole-vaulting. He started graduate study in 1927 under Sherrington. Speed still made chemical transmission at fast synapses seem impossible—it was “soup” versus “sparks.”

1.17 NOBEL PRIZE OF 1936

The Nobel Prize for Physiology or Medicine in 1936 went to Loewi (Fig. 1.5b) and Dale (Fig. 1.5c) “for their discoveries relating to chemical transmission of nerve impulses.” In his lecture in Stockholm Dale cited 11 papers from the group; he was an author on 5. Naturally enough some searched the literature to cite those who had scooped the Laureates. Chemical transmission had been suggested repeatedly, starting with Emil Heinrich Du Bois-Reymond (1818–1896), who had been a professor in Berlin. Such diggings are a diversion. It was not hard to think that transmission might be chemical; it was hard to devise experiments to test the hypothesis.

When the Germans entered Austria in 1938 Loewi and two of his sons were jailed until he gave up his Nobel Prize money as ransom. After several years in temporary positions he became a research professor at New York University (NYU). His wife was kept in Austria until 1941, when she turned over her family property in

Italy to the Nazis. The Nazis devastated the German universities and enhanced those abroad. In Britain it seemed to one younger neuroscientist “that through most of my scientific lifetime the most distinguished of my seniors mostly spoke with guttural accents” [50].

1.18 ELECTRIC ORGAN

The electric organ of *Torpedo* is made up of a huge stack of motor nerve endings and end plates in series. Albert Fessard (1916–2003) worked with the preparation, so Feldberg traveled over to France to collaborate [51]. They set up the spinal preparation in a shielded cage. The amplifiers, recording apparatus, and engineer were outside. Only Feldberg was within, cautioned not to touch the animal—doing so would generate a nasty electrical artifact. He was to inject ACh in the artery and call out “now.” He called but the engineer hastily stopped the recording. A huge artifact. The engineer was worried about damaging his amplifier. Feldberg was put into rubber gloves and boots as insulation. “Now.” Another artifact. Feldberg asked for another try. “Now.” No response. “Fine,” said Feldberg, “I injected saline.” With the next “now” he injected ACh; there was the already familiar huge voltage spike, which they now knew was the discharge of the electric organ [46].

The biochemist David Nachmansohn (1899–1983) was in France working on the electric organ [52]. He had trained with Otto Meyerhoff (1889–1951; Nobel Prize 1922) in Berlin but had been driven out by the Nazis. The electric organ had been found to contain astonishing concentrations of AChE. Nachmansohn began to purify it.

1.19 ECCLES, KUFFLER, AND KATZ

In 1937 Eccles returned to Australia as director of the Kanematsu Institute at Sidney Hospital, a department of diagnostic pathology whose director is expected to do research and is given financial support. Soon he had a small group. Stephen Kuffler (1913–1980) came from a landowning family in Hungary; they were wealthy but lost all in the Great Depression [53–55]. After graduation from medical school he worked as a pathologist, before hurriedly leaving Vienna. He had had some dangerous involvement in politics, which he thereafter shied away from. Unlicensed to practice medicine in England he went to Australia and was employed as a pathologist in the Sidney Hospital. Kuffler was invited for tennis on the court behind the Eccles’ house; after all he was a former Austrian tennis champion. Eccles persuaded him to join the laboratory to learn electrophysiology.

In late 1939 they were joined by Bernard Katz (1911–2003; later Sir Bernard; Fig. 1.6b), who was a Carnegie fellow [50]. Born in Leipzig, his father, a fur merchant, had come from Russia. At age nine he was at the top in the entrance examination for a prestigious gymnasium but was rejected because he was a foreign Jew. He was admitted to another school and then to the medical course at the University of Leipzig. When he received the M.D. in 1933 he was awarded a prize, given to him in private as a “non-Aryan.” He wanted to work on muscle under the

director of the Biophysics Laboratory at UCL, Archibald Vivian Hill (1886–1977; Nobel Prize 1922). Katz arrived in London in 1935 with a letter of introduction and £4 (a bit over £100 today). Within a year he and Hill published together. He received a Ph.D. at UCL and then headed for Sidney.

Eccles was working on mammalian muscle. Katz thought this far too difficult—frogs would be better. He remembered: “Stephen roaring with laughter when I showed him how to ‘take the frog’s trousers off’ ” (i.e., slip the skin off the rear legs) [55]. They placed the sartorius muscle in a chamber that had a maneuverable electrode in its floor, and stimulated the sciatic nerve. Poisoning transmission with +TC, they found areas on the muscle where they could record a localized potential change, the end-plate potential (EPP). The EPP was lengthened when the bathing solution also contained physostigmine. However, the electrical signals were complex and not easily interpreted.

World War II broke up the collaboration. Katz served in the Australian armed forces. Eccles worked on military problems. Kuffler received a research fellowship and did some further experiments on frog muscle, and in 1944 he and his Australian wife moved to the University of Chicago to the laboratory of Ralph Gerard (1900–1974).

1.20 NACHMANSOHN

Nachmansohn left for the United States before the war and in 1942 took a position at Columbia University [56]. He was working on the purification and properties of AChE, but it was difficult to get *Torpedo* for starting material. The U.S. Army asked him to investigate the effects of organophosphates on the enzyme. Some were known as potent insecticides and there was intelligence that the Germans were investigating them as potential war gases. Nachmansohn told them he would need a steady supply of electric eels from the Amazon, which an Army procurement officer dubbed “the craziest request of the war.” Nonetheless the eels came. Nachmansohn’s group showed that diisopropyl phosphorofluoridate (DFP) phosphorylates the serine on the active site of AChE and by the 1950s developed agents capable of reactivating the poisoned enzyme, such as pyridine-2-aldoxime methyl chloride (pralidoxime). Their crystallization of AChE opened the way for others, years later, to determine its structure. The reversible AChE inhibitors, such as physostigmine, bind to the active site of AChE where they are hydrolyzed just as ACh is, but at such a slow rate that they tie up the enzyme. On the other hand, the turnover of ACh by AChE is one of the fastest enzymatic conversions known.

Nachmansohn and his colleagues also showed that ACh is formed by extracts of the electric organ provided with choline and adenosine triphosphate (ATP) provided that fluoride is added to inhibit ATPase. This was revolutionary. There was no previous evidence that ATP is involved in synthetic reactions. The paper was rejected by three eminent journals. The enzyme, now called choline acetyltransferase, requires a coenzyme, which was identified by Fritz Albert Lipmann (1899–1986; Nobel Laureate 1953) as coenzyme A. Nachmansohn convinced himself that ACh is involved in axonal transmission. He convinced few others, but his dogged adherence to this mistake tends to obscure his achievements.

1.21 POSTWAR SCIENCE

World War II destroyed so much and so many, but it did increase public awareness of what scientists could do, so it was relatively easy afterward to persuade governments to keep money going to science. After a pause for economic recovery, the money began to flow and science was transformed. Figure 1.7a shows a U.S. example: the growth of the budget of the National Institute of Neurological Diseases and Stroke (NINDS). The growth in dollars is almost exponential, but the picture is altered when corrected for the decline in the purchasing power of the currency (Fig. 1.7a). The money fueled an enormous growth in the number of scientists (Fig. 1.7b and in the number of papers published on the actions of drugs on synapses (Fig. 1.7c). The American universities expanded to cope with the student veterans,

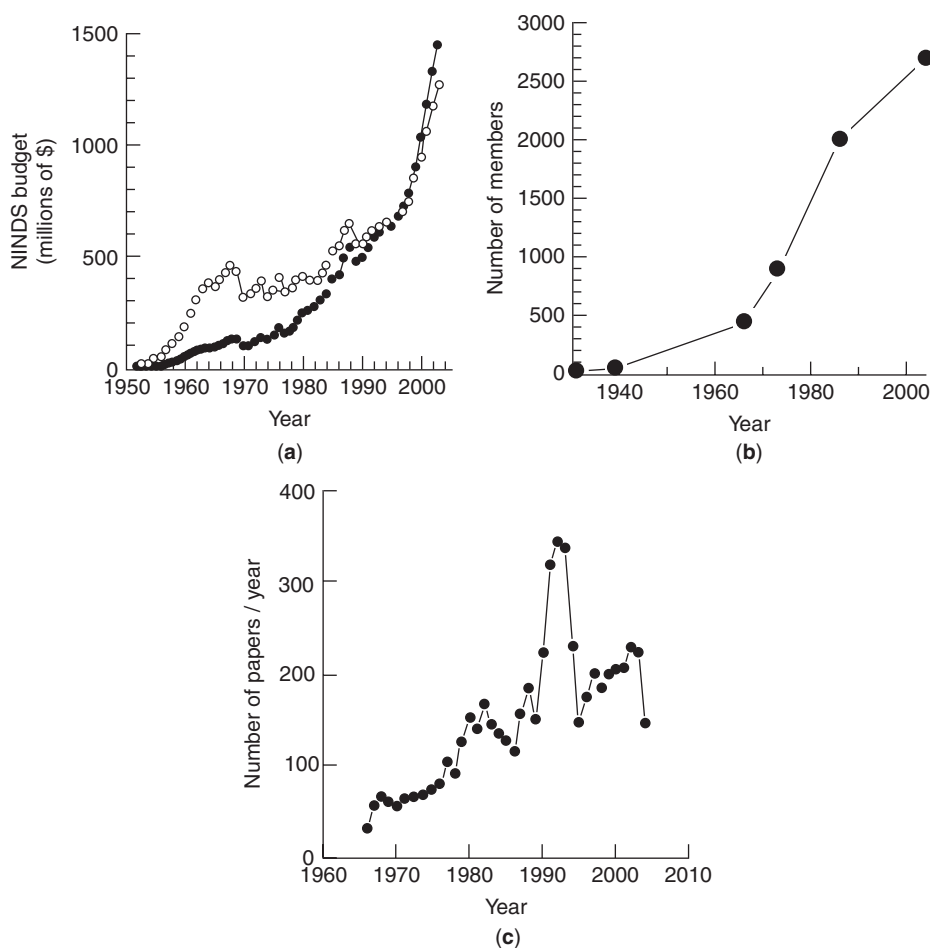

Figure 1.7 Some measures of research in neuropharmacology. (a) The budget of the NINDS filled circle (●); The budget corrected for the buying power of the dollar in 2000 (o) open circle in 2000. whose tuition and living expenses were paid for by the G.I. Bill, which surely must rank among the wisest legislations ever enacted.

1.22 BOVET

During the war +TC came into use to relax patient's muscles during surgery. Less anesthetic is needed for analgesia than for muscle relaxation so with +TC there is less toxicity. +TC has side effects, such as histamine release, so synthetic blocking agents were developed: some act like +TC and others act like nicotine, first stimulating and then blocking. A leader in the synthesis and testing of these compounds was Daniel Bovet (1907–1992; Nobel Laureate 1957). A native of Switzerland, he worked in France until 1947 when he and his wife, the pharmacologist F. Bovet-Nitti, moved to a new laboratory at the Istituto Superiore de Sanità in Rome. Bovet had a genius for thinking like a receptor, detecting the key operational parts of a complicated molecule such as +TC, and then synthesizing simpler compounds targeting the same receptor. One of his +TC substitutes is succinylcholine, which is hydrolyzed rapidly by ChE, so its blockade is readily reversible. He also pioneered in the development of histamine blockers and of antagonists for adrenergic receptors.

1.23 ION CHANNELS

Alan Lloyd Hodgkin (1914–1998; later Sir Alan) and Andrew Fielding Huxley (later Sir Andrew) showed how the squid giant axon generates action potentials by changes in Na^+ and K^+ permeabilities triggered by changes in membrane potential. The permeabilities are little changed by low temperature, which suggests that the ions flow through channels in the membrane. The Na^+ channel is blocked reversibly by local anesthetics and irreversibly by toxins such as tetrodotoxin, from the Japanese puffer fish, *Spherooides rubripes* [57]. The toxins were used to label the protein of channels for isolation and eventual cloning. Toxins that target the K^+ channel were discovered much later.

1.24 SOUP, NOT SPARKS

After the war Eccles wrote several influential reviews on the mechanism of synaptic transmission [58]. He conceded that neuromuscular transmission might have a chemical component but was adamant that the synapses in the CNS were electrical, both excitatory and inhibitory. As Kuffler said about him years later, “he has often been wrong, but only about important things” [54]. Chemical transmission at fast synapses would be on firm ground only when the electrophysiologists convinced themselves that it is so—until then the “soup” versus “sparks” argument would go on interminably.

The way was opened by Gerard and his colleague Gilbert Ling, a step that Gerard always downplayed because “techniques are not very important” [59]. They pulled glass microelectrodes by hand, filled them with half-strength Ringer, and manipu-

lated the tip toward a frog muscle fiber. Abruptly the pipette tip became negative to the external solution. They were measuring the resting potential of the cell. Glass fits comfortably with cell membranes, which reseal around the electrode after penetration. They could not measure action potentials, because their microelectrodes had such a high resistance that the time constant of the input stage of their electronics was too slow to follow a fast event. Hodgkin and William L. Nastuk (1917–1965) filled microelectrodes with 3 M KCl solution and used an amplifier input circuit able to cope with a high input resistance to record action potentials from skeletal muscle fibers [60]. Soon plans for making electromechanical micropipette pullers were published, then machines became commercially available, and the game was wide open.

Katz brought his Australian bride to London in 1946; he had been appointed Henry Head Fellow of the Royal Society. When the microelectrode flashed onto the scene, he returned to the neuromuscular junction, working with a graduate student, Paul Fatt. In +TC when the microelectrode was at the end plate and the nerve was stimulated, they recorded the EPP [61]. Raising the +TC concentration diminished the EPP; the drug was making less nicotinic acetylcholine receptor (nAChR) available. Anti-AChEs elongated the EPP. Using a second microelectrode to change the muscle membrane potential at the end-plate region, they showed that no EPP is seen at about 0 mV and that when the inside of the fiber was made positive the EPP was hyperpolarizing. This is because the ACh opens ion channels at the end plate that permit both Na^+ and K^+ to flow though, bringing the potential to about 0 mV, which is known as the reversal potential. The reversal was the conclusive evidence that at the neuromuscular junction (NMJ) transmission is chemical, not electrical. When ACh binds to the nAChR, it opens a chemically gated ion channel.

They then discovered small, randomly occurring depolarizations at the end plate. The depolarizations were eliminated by +TC and increased in amplitude and lengthened by anti-AChEs. They are miniature end-plate potentials (MEPPs). The ACh is released in packets or quanta of thousands of ACh molecules. Quanta may have been an unfortunate name, because it suggested to some that the packets contain a fixed number of transmitter molecules. In fact, the number can be varied over a wide range [61, 62]. The EPP is generated by the almost synchronous release of hundreds of quanta. The discovery of the MEPPs coincided with the development of tissue preparation techniques that permitted electron microscopists to see cell membranes as well as the vesicles in the motor nerve ending and in other chemical presynaptic endings.

Nastuk filled a microelectrode with ACh^+ and ejected graded amounts by adjusting electric current flow—iontophoresis [63]. ACh applied to the end-plate region opens the ion channels, but much higher concentrations are required at other parts of the muscle membrane, so the nAChR is concentrated at the end plate. Two ACh molecules usually bind to the nAChR to open the ion channel. The channel opens for a mean duration of 1 ms, determined first by statistical analysis of ACh “noise.” Other agonists open channels for different durations, depending on how rapidly they come off the nAChR. Erwin Neher and Bert Sakmann developed the patch technique to see individual channels opening. They started by observing nAChR channels on frog muscle fibers away from the end plate, where far fewer are found per unit area. They shared the Nobel Prize in 1991. Katz and Steven Thesleff showed that steady application of ACh results in a diminishing end plate current [64].

The nAChR is becoming desensitized. Other workers showed that in the desensitized receptor the affinity for ACh is increased.

1.25 ACTIONS OF +TC

+TC blocks ACh binding to the nAChR. But this is not the end of the story. The extent of the block of the nAChR by +TC varies with the potential across the end-plate membrane [65]. Part of the blocking action occurs because the drug enters open nAChR channels and plugs them. The amount of the charged drug entering the channel depends on the potential across the membrane. +TC also increases quantal output from stimulated motor nerve endings [66]. There are nAChRs on the presynaptic terminal; ACh and other agonists decrease quantal output and reduce the amount of ACh loaded into recycling vesicles [62]. There are receptors for a number of other transmitters and hormones on the motor nerve terminals [67].

Katz's papers are models to emulate: lucid, effective choice of short words and stripped of excess verbiage. His "perceptiveness in distinguishing the important from the unimportant was legendary" [50]. Such abilities were not always agreeable to his students; "there are many stories of experiences, sometimes quite traumatic, of presenting to him the first draft of a paper." He was careful and critical and eminently fair minded.

1.26 SYNAPTIC VESICLES

Synaptic vesicles containing ACh were isolated from mammalian brain and from the electric organ [68]. Victor P. Whittaker and others showed that the electric organ is a rich source and the vesicles unusually large. They found that along with the ACh the vesicles contain one ATP per four AChs and both are released by exocytosis. ATP itself is a transmitter at other junctions [69]. Studies on the electric organ elucidated the mechanism for loading ACh into the vesicles and showed that there are distinct pools of vesicles in the nerve endings [62, 68].

The most potent toxins known are made by *Clostridium botulinum*. A mouse has a 50 : 50 chance of being killed by an injection of 18 million toxin molecules [67]. They kill by blocking neuromuscular transmission. The toxins bind specifically to motor nerve endings and inject an active fragment into the cytoplasm. Transmission at other synapses is blocked if the active fragment is injected presynaptically. The toxins are Zn^{2+} -containing enzymes that target proteins involved in quantal release. Different bacterial strains produce different toxins that target different proteins, which enabled some of the proteins essential for exocytosis to be identified. Who then would have thought that these toxins would be used in huge amounts in cosmetic pharmacology?

1.27 CLONING THE nAChR

Electric organs are a splendid source of nAChR. It is made up of four subunits, and the first 54 amino acids in each of the chains were determined, a painstaking job with

the techniques available at the time. Shosaku Numa (1929–1992; Fig. 1.5d) and his group at Kyoto University prepared messenger ribonucleic acid (RNA) from electric organ and from 2.4 μg produced a complementary deoxyribonucleic acid (cDNA) library with about 200,000 clones [70]. They made small DNA probes for parts of the α -chain and then used them to search the library. It was a race of the kind seen more and more frequently since money expanded science: Laboratories in Britain, France, and the United States were working on the same lines. Numa's laboratory ran on 16-h days [71]. They first determined the composition of the α -unit; there are two of these in each nAChR, and they have ACh binding sites. Then they addressed the other three chains. The chains can reassemble spontaneously into functioning receptors. Other nAChRs are made up of different combinations of subunits. This was the first dazzling demonstration of the power of molecular neuropharmacology that figures so prominently in the rest of this book.

1.28 HOW CAN CHEMICAL TRANSMISSION BE SO FAST?

The venom of the Formosan snake, *Bungarus multicinctus*, contains a polypeptide, α -bungarotoxin, that binds irreversibly to the nAChR. The density of the nAChRs at the NMJ was measured with the electron microscope by labeling them with radioactive α -bungarotoxin. The density of the AChE was measured by reacting them with radioactive DFP [72]. Much of the AChE is on a fibrous network in the synaptic cleft. These densities, the rate constants for the reactions, an estimate of the number of ACh molecules in a quantum, and the diffusion equations were the raw material for a mathematical model of the generation of an MEPP [73]. When ACh is released from the vesicle into the narrow synaptic cleft, the local concentration is high. It diffuses across the gap saturating first the AChE in its path and then the nAChRs immediately opposite the release point. The remaining ACh diffuses along the end plate, combining with additional nAChRs to open more channels. The mean time for ACh to come off of the nAChRs is 1 ms. The nAChR is a low-affinity receptor, but because release is quantal, it is exposed to high concentrations of ACh, which it binds and then releases rapidly. Almost all of the ACh released from the nAChR is hydrolyzed by AChE before it can rebind.

1.29 ECCLES AND CENTRAL SYNAPSES

Eccles and his colleagues had been inserting fine metal electrodes into the cat spinal cord to record extracellularly from the cell bodies of motoneurons, so his group was ready to try glass microelectrodes. Astonishingly the submicroscopic tips survive being pushed through centimeters of spinal cord. They recorded intracellularly from their first motoneuron in June 1951 [34]. Activating a monosynaptic reflex by stimulating sensory axons from muscle stretch receptors, they recorded transitory depolarizations in the motoneurons. The depolarizations were named excitatory postsynaptic potentials (EPSPs). The more intensely the sensory nerve was stimulated, the larger the EPSP. When the EPSP reached a threshold level, the motoneurons fired an action potential. Next Eccles and his group inserted double-barrelled microelectrodes: one barrel to record potential changes and the second to pass a

current to set the potential of the motoneuron's membrane. Just as at the end plate, the EPSPs became hyperpolarizing when the inside of the cell was electrically positive. The reversal potential is about +3 mV. From the moment he first saw reversal the most ardent "spark" became an enthusiastic salesman for "soup."

Stimulation of an inhibitory pathway produced a slight hyperpolarization with a reversal potential of about -80 mV, an inhibitory postsynaptic potential (IPSP). By using a double-barreled microelectrode to ionophore ions into the motoneuron cell body, they showed that the reversal potential shifted to a more depolarized level after the Cl^- concentration was elevated, so the ion channel opened during inhibition is permeable to Cl^- . Hitherto they had thought that this inhibitory pathway was monosynaptic, but now they found an inhibitory interneuron, so the same cell was not both excitatory and inhibitory. They also discovered a presynaptic inhibitory mechanism which decreases the amount of transmitter released by an excitatory nerve ending.

Eccles shared the 1963 Nobel Prize with Hodgkin and Huxley. After 26 years of intense, driving, single-minded intracellular work on neurons he finally enjoyed 22 years of retirement in the Swiss mountains, working at a somewhat less intense pace on theory.

1.30 ADRENERGIC TRANSMITTERS IN CNS

Clearly there must be additional synaptic transmitters in the mammalian CNS. Obvious possibilities were adrenaline and noradrenaline. In 1954 Vogt demonstrated that noradrenaline is also found in the brain. The Nobel Prize in 1970 was shared by Ulf von Euler (1905–1983) and Julius Axelrod (1912–2004) for work on adrenergic systems. What a study in contrasts. Von Euler's father and godfather were Nobel Laureates in Chemistry and his mother was a noted botanist. He studied medicine at the Karolinska Institute; four years after matriculation he was an assistant professor of pharmacology. He worked in England with both Dale and A. V. Hill and also in Belgium and Germany. He became a professor at the Karolinska in 1939. Axelrod was born to poor parents in New York City [74]. He obtained a bachelor's degree in chemistry at the City College of New York, which at that time had no tuition charges. Graduating in 1933, at the nadir of the depression, he was rejected by medical schools so he worked as a lab assistant, a chemist in industrial hygiene where he lost an eye in a lab accident, and then in a research division of NYU. Along the way he earned an M.A. at night. At NYU his boss was Bernard B. Brodie (1907–1989): "generally called Steve Brodie. This referred to a saloon keeper named Steve Brodie, who at the beginning of the previous century had jumped off the Brooklyn Bridge to win a bet" [74a]. Brodie turned Axelrod onto the joys of research. In 1949 they moved to the newly established National Heart Institute in Bethesda. Axelrod was appointed head of pharmacology there in 1955, the same year he received a Ph.D. degree from the George Washington University.

Both von Euler and Axelrod measured amines by their fluorescence and put radioactive labels on compounds to follow their movements and metabolic transformations. Von Euler found that noradrenaline is packaged in large granules in adrenergic nerve endings, analogous to the smaller ACh-containing vesicles

at cholinergic endings. Axelrod showed that noradrenaline is broken down by monoamine oxidase but that most of the noradrenaline released from adrenergic neurons is transported intact back into cells—a new and unexpected mechanism for terminating transmitter action. The transmitter taken back into the nerve terminal is repackaged and released again. The uptake is blocked by cocaine, which accounts for its ability to potentiate sympathetic stimulation.

In the late 1940s numbers of derivatives of iminodibenzyl were synthesized and tested for their effects. A few with sedative properties were used in clinical trials. One of these, imipramine, had no quieting effect on agitated patients but by lucky chance was found to benefit depressed patients. It became the model compound for the tricyclic antidepressants. Axelrod showed that they block the reuptake of noradrenaline.

1.31 CARLSSON

Arvid Carlsson (Nobel Laureate 2000) was working on Ca^{2+} metabolism. At age 32 he applied for an associate professorship but was rejected on the ground that his subject was at a dead end. Stimulated so forcefully to shift fields, he went to work with Brodie for five months in 1955. When Carlsson arrived in the laboratory they were investigating 5-hydroxytryptamine (5-HT). It had been discovered in serum and in the gut; now they found it in the brain. They measured it with the spectro-photofluorimeter, which they had devised for detecting amines in biological samples.

They were also studying reserpine, an alkaloid from *Rauwolfia serpentina*, a shrub found in the Indian subcontinent. It had been used for centuries in Indian medicine but had just been introduced in the west for the treatment of hypertension. Its adverse reactions were sedation and, less commonly, psychotic depression. Brodie and his collaborators found that reserpine depleted the brain of 5-HT. Back in Sweden Carlsson and his collaborators showed that reserpine depleted brains of noradrenaline and that after treatment stimulated sympathetic postganglionic axons released less transmitter.

They wanted to see whether the reserpine effect could be reversed by restoring catecholamines to normal levels. Catecholamines do not penetrate the blood–brain barrier, so they decided to give a precursor that can penetrate, DOPA (3,4-dihydroxyphenylalanine). DOPA put reserpine-treated rabbits back on their feet in no time. When they measured the noradrenaline in these brains they were astonished to find it still was low. Reserpine is antagonized by monoamine oxidase inhibitors, so they reasoned that DOPA must be converted to an amine. The first step in the pathway between DOPA and noradrenaline is dopamine. Dopamine had never seemed of interest because it has little effect on tissues innervated by the autonomic nervous system. They developed a method to measure dopamine. In the brain there is more dopamine than noradrenaline, and dopamine disappears with reserpine treatment and is restored by DOPA. The effects of reserpine treatment resemble those of the Parkinson syndrome, and they found that normally dopamine is in high concentration in the basal ganglia, so they suggested that DOPA might be useful in treating the disease.

Flushed with success, Carlsson went to London in 1960 to present at a symposium. “The central figure was Sir Henry Dale, a Nobel Laureate aged 85

but still remarkably vital. He dominated the scene, and the participants, many of whom were his former students, treated him with enormous respect, like school children their headmaster, although many of them had indeed reached a mature age." Carlsson's conclusions were summarily dismissed. "Dale expressed the view that L-DOPA is a poison, which he found remarkable for an amino acid" [74a]. Dale's group pitched in to dismiss his work with equal certainty. How Carlsson must have enjoyed recounting this in his own Nobel lecture.

Carlsson and his co-workers devised histochemical methods to see precisely where catecholamines are in the brain. Within a few years they localized dopamine, noradrenaline, and 5-HT. At the next major meeting, in 1965, there was no argument whether or not these amines were important in the brain. Other investigators then carried into the clinic the role of the loss of dopamine in Parkinson's and its restoration by L-DOPA.

As we have seen, the tricyclic antidepressants, such as imipramine, were discovered in the 1950s and in the early 1960s were found to block noradrenaline uptake into nerve terminals. In the late 1960s Carlsson and collaborators found that they also blocked 5-HT uptake and developed selective inhibitors for this transporter. The best known is fluoxetine (Prozac).

1.32 SECOND MESSENGERS

Although many transmitters open ion channels, there must be other ways for them to act on target cells. Adrenergic transmitters or hormones alter cell metabolism, for instance, stimulating the liver to break glycogen down to glucose. Carl Ferdinand Cori (1896–1984) and Gerty Theresa Cori (1896–1957; Nobel Laureates 1947) elucidated the pathway by which glycogen is broken down to glucose. The enzyme phosphorylase is the rate-limiting step in glycogen breakdown. Earl W. Sutherland (1915–1974; Nobel Prize 1971) found that adrenaline increased the activity of phosphorylase in homogenates of liver cells. These homogenates also contained an enzyme that brought phosphorylase activity back to baseline without significantly altering its molecular weight. This enzyme inactivated phosphorylase by removing phosphate. In liver slices exposed to adrenaline phosphorylase becomes labeled with radioactive phosphate. The enzyme is turned on by being phosphorylated and turned off when the phosphate is removed.

Phosphorylase was not activated by adding adrenaline to homogenates. But when they also provided ATP and Mg^{2+} to the homogenates, adrenaline activated phosphorylase. They centrifuged the homogenate and worked with the soluble fraction, which contains the phosphorylase. Adrenaline did nothing. The crucial experiment was to resuspend the particulate fraction in ATP and Mg^{2+} and then expose it to adrenaline. This suspension contained a heat-stable substance that activated phosphorylase when added to the soluble fraction. The activating factor was precipitated by Ba^{2+} , so it was probably a phosphate compound. With the available techniques, it promised to be a long job characterizing the activator from the trace amounts formed by the particulate fraction. They showed that it was an adenine ribonucleotide. Sutherland wrote to a friend telling him what he knew of the properties of his activator. The friend recalled a description he had received from another investigator of a derivative produced when ATP is digested in barium

hydroxide. The properties seemed identical. This made it much easier to characterize the activator as adenosine 3',5'-monophosphate (cAMP).

Hence, adrenaline acts on a receptor on the cell membrane. This activates the enzyme adenylyl cyclase, so cAMP is formed. It acts as a second messenger that activates the kinase that activates phosphorylase. The cAMP is destroyed by phosphodiesterase, which is inhibited by alkaloids such as caffeine and theophylline. Sutherland's discoveries flung open the door for the enormous quantity of work that still continues on cellular signaling systems. An offshoot was the characterization of muscarinic ACh receptors, the identification of their second messengers, and establishing that these messengers could open some ion channels and close others. Trying not to move too far from the past, I shall merely note that the Nobel Prizes to Edmond H. Fisher and Edwin G. Krebs in 1992, Alfred G. Gilman and Martin Rodbell in 1994, and Arvid Carlsson, Paul Greengard, and Eric R. Kandel in 2000 were all for work building brilliantly on Sutherland's.

1.33 AMINO ACID TRANSMITTERS

Some Crustacean muscles have a dual innervation: excitatory and inhibitory. Neither excitation nor inhibition is affected by adrenergic or cholinergic drugs. Picrotoxin, a convulsing drug isolated from the seed of *Anamirta cocculus*, a climbing shrub from southeast Asia, blocks the effects of stimulating the inhibitory axon [75]. By the late 1950s such preparations could be ordered from the catalog, because enough money was going into biomedical research to support chemical companies specializing in the research market. The active part of this preparation, which has a difficult chemistry, is picrotoxinin (Fig. 1.2). Other workers had been looking in brain homogenates for small molecules that might be transmitters. One possibility was the unusual amino acid γ -aminobutyric acid (GABA). It inhibited excitation and its action was blocked by picrotoxin.

What about the excitatory transmitter for crustacean muscle? A Columbia medical student spent a summer seeing which amino acids caused the muscles to contract, finding that glutamate was the by far the most effective [76]. This was one of the first steps in proving that glutamate is the excitatory transmitter. Synapses in the mammalian CNS were investigated by ejecting test chemicals by iontophoresis [34]. Glutamate depolarized motoneurons. At first it was thought that this action might be nonspecific, but its identification as a transmitter was supported by the crustacean results. Aspartate is also an excitatory transmitter in the CNS. Both GABA and glycine are inhibitory transmitters in the vertebrate CNS.

1.34 KUFFLER

One of the laboratories working to expand the list of transmitters was Kuffler's [53–55]. He liked to shift preparations every few years, picking a new one that seemed promising and that tested his dissecting skills — an approach that would not survive today's grant evaluation system. They studied Crustacean stretch receptors and showed that they receive an inhibitory innervation from the CNS. The inhibition was blocked by picrotoxin and mimicked by GABA. They fractionated CNSs from 550

lobsters and tested the fractions for inhibitory molecules [77]. By far the most potent was GABA, which they then showed was much more concentrated in inhibitory than in excitatory axons. They worked on the snake neuromuscular junction, treating the preparation with collagenase and then pulling the nerve terminals away. The muscle fiber was covered with oil and droplets of solution slid onto the naked end plate. They determined that somewhat fewer than 10,000 ACh molecules were needed to generate a MEPP [78]. Kuffler's last contribution was the discovery of a "late slow" EPSP in postganglionic cells in frog autonomic ganglia produced by the release from the presynaptic neurons of a peptide resembling luteinizing hormone releasing hormone. This was one of the first demonstrations that more than one transmitter can be released at synapses. Further work revealed how complicated transmission is in the autonomic ganglia, with a series of EPSPs with different time scales and an IPSP as well and, of the importance of peptides released at synapses.

Kuffler had learned the lesson of Dale's group at the NIMR: how effectively work on the nervous system could be done by a closely interacting combination of specialists—physiologists, pharmacologists, anatomists, and biochemists—all backed by a first-rate technical staff. In 1959 Kuffler and nine colleagues established a section in the Department of Pharmacology at the Harvard Medical School. The chair was Otto Kraye (1899–1982). Kraye was not Jewish but left Germany when he rejected a chair from which a Jew had been ejected. After Kraye died Kuffler's section became the Department of Neurobiology at Harvard. His admiring colleagues regarded the establishment of the new department as a miraculous navigation of the shoals of academic politics. It became a model for many others around the world. Kuffler was skilled at keeping a group of highly distinguished and hard-driving researchers at peace with one another. Humor was his main weapon. His colleagues restricted him to "two puns a day," but this rule was frequently violated.

1.35 END OF THE ERA

Dale left the laboratory after receiving the Nobel Prize. When Wellcome died, Dale was named in his will as one of the five trustees for the Wellcome Trust [37]. The other scientific trustee was Elliott, who had become professor of medicine at UCL. Two years later Dale became the chairman of the Trust. It was a difficult and challenging job. Wellcome left everything to the Trust, which was charged with running the company, dealing with his vast collections, and supporting research. The will was lengthy and detailed but was vague on crucial points and even self-contradictory. Moreover, the business was not what it had been; Wellcome had paid it too little attention in his last years. The death duties were enormous. The trustees took the hard decision that they had no money for science—first they must pay off the duties and invest to restore the company's health. In the foundation's first 20 years only £1 million was disbursed for research. The company was saved by its U.S. branch, which had strong research—Gertrude B. Elion (1905–1998) and George H. Hitchings (1918–1999) were Nobel Laureates in 1988—and excellent management. After Dale retired as a trustee on his 85th birthday, the Trust was directed by a series of able men, who continued to plow profits back into research. It worked. By 1991 the Wellcome Trust was disbursing over £100 million a year to support scientific research. Dale died eight years after his retirement, at age 93.

Feldberg, like Kuffler, was known for his sense of humor. His after-dinner speeches to the Physiological Society were classics. In his nineties he was still experimenting. He permitted a group to film his work, purportedly for educational use. In truth they were antivivisection activists who reported him to the British Home Office. His license to use animals was revoked. He died soon after, having endured the very problem that had so plagued Claude Bernard a century and a half before.

1.36 CONCLUSIONS

In a little more than a century enough of the mechanism for chemical synaptic transmission was worked out to make much of neuropharmacology coherent. Most of the crucial observations came from experiments with poisons from nature. We have progressed from the observation that curare blocks transmission from motor nerve to muscle to the precise identification of the +TC binding sites on the nAChR.

My view is that the advance of science has been like the flow of water down a channel. Starting as a trickle for several centuries, swelling to a ripple in the seventeenth century, and now surging forward as a towering wave. The energy for building up this surge has come from the growth of human population and productivity, starting at about 1700 and continuing unabated to the present. I have written about the part of the scientific surge that is my subject by assigning progress to a few leaders riding on the crest of the wave, ignoring thousands of others. This is manifestly unfair, especially because many of the archetypes I have chosen were friends or acquaintances. Otto Loewi was an especially dear friend and thanks to his vivid descriptions I feel as though I have rubbed shoulders with Starling, Langley, Schmiedeberg, and others of that generation. My defense is that without archetypes you cannot convey any idea of what people actually did, what they were like, and the conditions in which they worked. I can only apologize to the multitude whose contributions have been ignored. When I studied the lives of my archetypes, the importance of things I had taken for granted became unmistakable: laboratories, money, fellowships, scientific meetings and societies, friends, students, collaborators, journals, and, at the top of the list, teachers. Which is why—again picking arbitrary examples—I have given each of these at least a nod.

The astonishing success and growth of neuropharmacology have been underwritten by enlightened governments. There is also a bleak reverse side in the story. Progress is not inevitable. German science was fostered by thoughtful and supportive governments. The Nazis distorted scientific policy for their abhorrent political aims. They discarded admirable people, crippling German science while unwittingly benefiting their foes. Some argue that scientists should stick to their laboratories and let others tend to the bigger picture. History does not agree.

2.1 INTRODUCTION

The “neuron doctrine” embodies concepts first proposed by Santiago Ramon y Cajal, namely that neurons are discrete cellular entities that function semi-independently and that must communicate with one another in order to sustain the processing functions of the central nervous system [1]. Despite the early evidence in support of the neuron doctrine, it was unclear how neurons actually accomplished intercellular signaling.

The multipolar anatomy of neurons spawned the concept that some domains of the neuron were exclusively local to the region containing the cell body, while others could be long and extend into distant regions of the nervous system. Combined with subsequent electrophysiological studies that defined the properties of passive and active current spread in neurons, it was thought that axons were primarily responsible for “output”-like functions of neurons, while dendrites could generally be considered to be “input” zones. Moreover, the advent of ultrastructural studies enabled, for the first time, clear evidence that there were close anatomical appositions between a variety of neuronal domains. This apposition (which corresponds to Sherrington’s “synapse”) then represents the milieu in which intercellular communication occurs.

The exchange of chemical signals across the synaptic space is the major mechanism by which intercellular signaling occurs. In the early part of the twentieth century, Otto Loewi performed experiments in which he stimulated an afferent (“presynaptic”) nerve fiber and attempted to determine how that stimulation affected the target (“postsynaptic”) tissue. He demonstrated, for the first time, that a chemical, diffusible signal (in this case acetylcholine) was able to mimic the cellular effects of stimulation of the presynaptic tissue. His studies set the stage for the concept that intercellular signaling in the nervous system was chemical in nature.

We now know that there are scores of chemical entities in the brain that serve as intercellular signaling molecules [2]. Initially, a set of molecules, mostly amino acid-derived chemicals [acetylcholine, monoamines, glutamate, γ -aminobutyric acid (GABA)], were identified as neurotransmitters that were regulated, from biosynthesis to release to inactivation, via very similar basic biochemical mechanisms. Subsequently, it became clear that these biogenic amines were only one way that neurons signaled one another, and new chemical species have been identified which obey few of the extant rules discovered through the study of the classical neurotransmitters.

The question then becomes, “what is a signaling molecule and what is not?” The criteria by which neurotransmitters are identified [2] are presented here and discussed in detail in the following sections. First, a chemical must be synthesized, either enzymatically or transcriptionally, by the neuron purported to be releasing it. Second, the chemical should be released from the neuron in a manner related to its neuronal activity (e.g., stimulation of the neuron should lead to measurable release of the chemical entity). Third, the direct application of the chemical to the postsynaptic cell should produce a physiological or biochemical effect similar to that of stimulation of the presynaptic neuron believed to be releasing the molecule. Fourth, the postsynaptic cell should express receptors that are specific for the released chemical. Finally, there should be mechanisms for postutilization inactivation of the released chemical. Taken together, these bits of evidence support the notion that a chemical found in a neuron is the (or one of the) mechanism(s) by which that cell communicates with its synaptic targets.

TABLE 2.1 Chemical Neurotransmitters

Classical neurotransmitters	
Biogenic amines	Norepinephrine (noradrenaline), dopamine, epinephrine (adrenaline), serotonin, tryptamine, histamine, acetylcholine
Amino acids	GABA, glutamate, aspartate, glycine
Neuropeptide neurotransmitters	
Peptides	Neurotensin; enkephalin, endorphin, dynorphin; neuropeptide Y; cholecystokinin; tachykinins; thyrotropin-releasing hormone; vasoactive intestinal peptide
Growth factors	Brain-derived neurotrophic factor, NT-3 and NT-4, nerve growth factor, glial cell line-derived neurotrophic factor, ciliary neurotrophic factor, epidermal growth factor, insulin, fibroblast growth factor
Unconventional neurotransmitters	
Nucleosides	Adenosine, adenosine triphosphate (ATP)
Steroids	Estrogen, cortisol, allopregenalone
Gases	NO, CO
Endocannabinoids	Anandamide, 2-arachidonylglycerol

Today, we recognize a cadre of neurotransmitter molecules that fall into three general categories, including classical neurotransmitters (biogenic amines and amino acids), peptides and growth hormones, and unconventional neurotransmitters (Table 2.1). In this chapter, we will describe these basic mechanisms that are required for chemical signaling in the nervous system. Biosynthesis, storage and release, receptor activation, reuptake, and catabolism are all important parts of the life span of the neurotransmitter, and each of these steps is critical to maintaining the integrity and discreteness of chemical signaling. Perhaps most importantly, each of these steps represents levels at which individual differences in signaling, in some cases affecting behavioral function, can arise, and pharmacological strategies can be tailored to regulating each of these levels of function.

2.2 TRANSMITTER SYNTHESIS

Biosynthesis is the first step involved in the utilization of a chemical signal. For all the known chemical signaling molecules, the chemical is generated specifically for the purposes of synaptic release. Even amino acid molecules generally involved in intermediary metabolism, such as glutamate, are biosynthesized at their release zone to generate a pool of transmitters dedicated to release. Therefore, biosynthesis represents the entry point at which a molecule dedicated to release becomes initially partitioned from the surrounding biochemical environment.

2.2.1 Amine Transmitters

The most commonly studied neurotransmitters are the amino acid–derived, small-molecule (“classical”) neurotransmitters. The production of most classical neurotransmitter substances is enzymatic in nature, occurs in the cytoplasm, is regulated by neuronal activity and intrasynaptic mechanisms coupled to signal transduction pathways, and occurs in advance of demand. Activity of synthetic enzymes can be dynamically regulated on multiple time scales: from the subsecond to the seasonal. Discrete regulatory mechanisms (transcriptional and posttranslational) act to rheostatically affect production at these various time scales.

Specific enzymes are responsible for the production of each neurotransmitter species (Table 2.2); indeed, these synthetic enzymes are sometimes expressed with sufficient selectivity to permit immunohistochemical identification of neurotransmitter phenotype. For example, cholinergic neurons are uniquely identified by immunopositive labeling for the enzyme, choline acetyltransferase (ChAT), while GABAergic neurons are recognized by staining for glutamic acid decarboxylase (GAD). In other cases, however, neurotransmitters share synthetic enzymes and pathways (Table 2.2; e.g., dopamine is the precursor for noradrenaline, which is the precursor for adrenaline, resulting in partially overlapping protein expression patterns).

The classical neurotransmitters (Table 2.1) are all amino acid derived; the enzymatic steps involve the conversion of a precursor amino acid with no or low affinity for the postsynaptic receptors into an active form which can exert transsynaptic effects (Fig. 2.1). Therefore, this productive process requires sufficient enzymatic activity (related to total numbers of enzymes present and their kinetic activity), sufficient precursor availability, and the availability of required cofactors [2]. For example, the ability of tryptophan hydroxylase (Table 2.2) to generate the indoleamine intermediate 5-hydroxytryptophan (which is subsequently transformed to serotonin) is related to the enzyme’s catalytic potential, the available levels of the precursor tryptophan (which are dependent upon dietary intake), and the presence of required cofactors such as tetrahydropteridine (a hydrogen donor), molecular

TABLE 2.2 Biosynthesis of Classical Neurotransmitters

Neurotransmitter	Synthetic Enzyme (and Cofactors)
Glutamate	Glutaminase (glutamine → glutamate)
GABA	Glutamic acid decarboxylase (glutamate → GABA)
Glycine	Serine hydroxymethyltransferase (serine → glycine)
Acetylcholine	Choline acetyltransferase (choline → acetylcholine)
Serotonin	Tryptophan hydroxylase (tryptophan → 5-hydroxytryptophan) Aromatic acid decarboxylase (5-hydroxytryptophan → serotonin)
Dopamine	Tyrosine hydroxylase (tyrosine → L-DOPA) Aromatic acid decarboxylase (L-DOPA → dopamine)
Norepinephrine	Tyrosine hydroxylase (tyrosine → L-DOPA) Aromatic acid decarboxylase (L-DOPA → dopamine) Dopamine-β-hydroxylase (dopamine → norepinephrine)
Histamine	Histidine decarboxylase (histidine → histamine)

Figure 2.1 Synthesis and vesicular storage. Neurotransmitters can be biosynthesized locally at the release zone (classical transmitters, gaseous transmitters, and endocannabinoids) or produced within the cell body and transported to the release zone in a dense core granule (peptides and growth hormones). CO: carbon monoxide; NO: nitric oxide; EC: endocannabinoid.

oxygen, and Fe^{2+} [3]. As will be discussed later, the synthesis of some neurotransmitters also depends upon surrounding concentrations of the end product through a set of feedback inhibitory mechanisms.

Of course, neurotransmitter production rates are also under the control of neuronal activity, usually through elevations in cytosolic concentrations of Ca^{2+} , which in turn activate calcium-calmodulin-dependent protein kinase II (CaMKinase-II) and protein kinase C (PKC). Elevations in intracellular Ca^{2+} levels, which are associated with high levels of neuronal activity, will activate CaMKinase-II and PKC, leading to increased phosphorylation of the synthetic enzymes (e.g., tryptophan hydroxylase) and consequent change in their catalytic activity [4]. This is the primary mechanism by which neurons couple action potential activity with neurotransmitter biosynthesis rates.

Conversely, cytosolic concentrations of produced transmitter (the end product) may feedback inhibit further enzymatic activity [2]. The mechanisms for end-product inhibition are diverse but can depend upon competitive inhibition of the interaction of the required cofactors with the synthetic enzyme. Although this mechanism may be thought of as translating lower neuronal activity (and hence increases in the vesicular storage pool) of the transmitter into less synthesis, this is generally not the case. As discussed in Section 2.6, a decrease of release typically leads to greater synthesis through a release of feedback inhibition of synthesis mediated by pre-synaptic autoreceptors.

These posttranslational mechanisms represent the primary substrates by which rapid and transient changes in neuronal activity may be translated into variations in neurotransmitter production. However, there are also transcriptional changes in synthetic enzymes that are associated with long-term alterations in neuronal activity. For example, stress instantaneously activates noradrenergic neurons and increases the activity of the rate-limiting catecholamine synthetic enzyme tyrosine hydroxylase (Table 2.2) through phosphorylation-dependent mechanisms. Additionally, chronic stress can lead to an overall increase in tyrosine hydroxylase content in noradrenergic neurons: a compensation to the sustained activation of the system by the environmental challenge [5]. These changes depend upon major transcriptional regulators related to heightened neuronal activity, including cyclic adenosine monophosphate (cAMP) response element binding protein (CREB) and the AP-1 complex.

Synthesis generally occurs in advance of vesicular packaging (see Section 2.3), although there is some evidence that it can also occur within vesicles (e.g., synthetic enzymes such as dopamine- β -hydroxylase can be found within vesicles and released during exocytosis; [6]). The intravesicular sequestration of the chemical signaling molecules is typically accomplished by a set of defined vesicular transporters (Fig. 2.1; also see Section 2.3).

2.2.2 Neuropeptides, Neurotrophins, and Growth Factors

Neurons release a variety of protein messengers in a typical action potential-dependent, exocytotic manner. These peptides include neuropeptides, hormones, and growth factors/neurotrophins. These peptide transmitters are frequently synthesized by cells that otherwise enzymatically generate classical amino acid-derived transmitters, a phenomenon known as colocalization.

Synthesis of these molecules is transcriptional in nature and occurs within the cell body prior to packing into dense core granules, followed by subsequent transport to the release sites (Fig. 2.1 [6]). With this in mind, the regulatory mechanisms governing peptide synthesis are slower in nature than those in control of classical transmitter synthesis, although there may still be posttranslational mechanisms that can be recruited at the synaptic terminal to rapidly increase “active” forms of the peptide [7].

Neuropeptides are frequently transcribed and translated into long, inactive (“prepro”) forms which are subsequently edited down to the final, active forms [7]. During translation, the peptides are read out into the endoplasmic reticulum, transported into the Golgi apparatus, and then packaged into so-called dense core granules. Conversion to the final, active forms of the peptide can occur within the dense core granules and involves Ca^{2+} - and pH-regulated prohormone convertases

[8]. These posttranslational events can allow intracellular events (like neuronal activity) to govern the rate of production of active peptide forms.

Neurotrophins and growth factors [e.g., brain-derived neurotrophic factor (BDNF), nerve growth factor (NGF), NT-3] tend to be larger proteins than hormones or neuropeptide transmitters. These molecules are synthesized translationally via many of the same mechanisms governing neuropeptide hormones. Some are translated into the endoplasmic reticulum and then packaged into dense core granules in the Golgi apparatus; like neuropeptides, others are not [9]. This latter pool can be moved to the release sites for signal-evoked release of the proteins.

2.2.3 Endocannabinoids

Lipid derivatives are also released in an “on-demand” fashion by cells to exert effects across a synapse; both anterograde and retrograde signaling is possible for these systems, although the latter appears to be more common (Fig. 2.1). Collectively, a group of arachidonic acid-conjugated lipids, including anandamide and 2-arachidonylglycerol, constitute the so-called endocannabinoid messengers [10].

These agents are neither synthesized in advance of utilization nor packaged into vesicles in a classical manner. The enzymes involved in the biosynthesis of endocannabinoids are Ca^{2+} regulated, and synthesis therefore occurs on demand. In subcellular domains capable of endocannabinoid secretion, a sudden increase in Ca^{2+} -mediated depolarization will activate the necessary enzymes (e.g., *N*-acyl-transferase and phospholipase D) which transfer an arachidonic acid group to phosphatidylethanolamine; the final product of this system is anandamide, which can enter the synapse through direct movement across the lipid membrane. 2-Arachidonylglycerol is synthesized from the activation of phospholipase C and diacylglycerol lipase.

2.2.4 Gaseous Transmitters

Gases, including carbon monoxide (CO) and nitric oxide (NO), are important participants in intercellular signaling in the brain [11, 12]. NO and CO can be synthesized, enzymatically, by NO synthase and heme oxygenase, respectively (Fig. 2.1). NO synthase is Ca^{2+} activated, and thus NO is synthesized on demand. Neither of these molecules is subsequently stored in vesicles, and they are capable of direct diffusion across the plasma membrane.

2.3 TRANSMITTER PACKAGING

2.3.1 Classical Transmitters

Cytosolic synthesis of transmitter is typically followed by the transport and seclusion of transmitter into vesicles (Fig. 2.1). This movement of the transmitter is mediated by a defined set of vesicular transporters, which are typically 12 transmembrane-spanning domain proteins [13] with reasonable homology to the membrane transporters (see Section 2.7). The amino acid transmitters (Table 2.1) are moved into vesicles by a set of transporters that take advantage of the electrochemical gradient across the vesicular membrane. By contrast, another set of vesicular transporters

(including those for the biogenic amines; Table 2.1) undertake the reverse transport of H^+ molecules for neurotransmitter.

Inhibition of vesicular transporters eventually leads to a disruption of action potential-dependent neurotransmitter release. For example, prolonged inhibition of vesicular monoamine transporters by reserpine leads to a dramatic and long-lasting impairment in the pool of monoamine transmitters available for on-going activity-dependent release [2]. This is because the action potential-dependent release of these transmitters generally depends critically upon this vesicular pool of transmitter (Section 2.4.1).

2.3.2 Peptide Transmitters and Growth Factors

Many of the neuropeptides that are secreted in response to action potential activity and that mediate cell–cell signaling, in this sense, are stored in vesicles called dense core granules. However, this packaging occurs after translation; most of these peptides are read out into the endoplasmic reticulum (ER) during translation [6–8]. Once in the ER, they can be moved to the Golgi apparatus for packaging into the dense core granules which are in turn transported down to the synaptic terminals or release zones. Again, posttranslational modifications are possible within the granules.

2.3.3 Endocannabinoids, Purines, and Gaseous Transmitters

Many of the most recently discovered signaling molecules, including the endocannabinoids (e.g., anandamide and 2-arachidonylglycerol), the purines (adenosine), and gaseous molecules (CO, NO), do not necessarily require vesicular storage for release. Endocannabinoids and gaseous molecules can diffuse across the membrane using passive mechanisms, while adenosine can be “pumped” out of the release zone via bidirectional nucleoside transporters [10, 11, 14]. Novel mechanisms of neurotransmitter secretion are undoubtedly possible.

2.4 SYNAPTIC RELEASE

2.4.1 Vesicle-Dependent Release

Vesicles full of transmitter are prepared for release in advance of arrival of an action potential at the release zone in order to lessen the time required to achieve synaptic release (Fig. 2.2). Vesicles can be held in place at the presynaptic release zone by a complex of proteins known as soluble N-ethylmaleimide-sensitive factor attachment protein receptors (SNAREs) [15]. This complex involves protein–protein interactions between substrates expressed within the vesicular wall (e.g., synaptobrevin) and substrates within the cell membrane (e.g., syntaxin and SNAP-25). After this initial association occurs (docking), the hydrolysis of ATP by a SNARE-associated ATPase leads to destabilization of the SNARE complex and “priming” or a prefusion bridging of the vesicular and plasma membranes.

Another vesicular protein, called synaptotagmin, appears to be the Ca^{2+} -sensing protein that translates the action potential-dependent rise in cytosolic Ca^{2+} ions in the presynaptic terminal into final fusion and exocytosis [16]. Because the vesicles are already docked and primed, the influx of Ca^{2+} , which probably occurs through

Figure 2.2 Synaptic release. Filled vesicles, which generally exist in excess of demand, are slowly moved to the release zone, where they are docked, primed, and partially fused prior to action potential generation. Influx of Ca^{2+} in response to an action potential mediates the final phase of vesicular fusion and exocytosis. Additionally, plasma membrane transporters can mediate the secretion of transmitter in a Ca^{2+} -independent fashion. NT: neurotransmitter.

channels spatially proximate to the SNARE complexes, leads to very rapid exocytosis. Therefore, there is a “microenvironment” present which is designed to minimize the time required for cell–cell signaling.

2.4.2 Vesicle-Independent Release

As noted above, some intercellular signaling molecules are capable of direct diffusion across the plasma membrane, meaning that their secretion is independent of typical vesicular storage and exocytosis. These molecules include the gaseous neurotransmitters and endocannabinoids. Their secretion is still tied to action potential generation because their synthesis is Ca^{2+} gated (Fig. 2.1).

However, even neurotransmitters typically stored in vesicles can be secreted in a vesicle-independent manner under certain circumstances. For example, the plasma membrane transporters (discussed in detail in Section 2.7) are driven, in part, by

substrate concentration gradients, which typically point from outside the cell to inside the cell. However, under circumstances where cytosolic neurotransmitters rise dramatically, for example, when vesicular transporters are disrupted and synthesis is not followed by rapid synaptic packaging, the membrane transporters can lead to an action potential-independent mode of secretion (Fig. 2.2; [17, 18]). The demonstration of this phenomenon typically depends upon pharmacological manipulations of vesicular transporter function; however, it remains possible that this form of secretion can occur under physiological conditions.

2.5 POSTSYNAPTIC RECEPTORS

Once secreted into the synaptic space, neurotransmitters must bind to and alter the activity of their receptor or effector proteins. There are four major classes of receptors that mediate the effects of release chemical substances (Fig. 2.3). These include ionotropic (ligand-gated) channels, metabotropic (G-protein-coupled) receptors, tyrosine kinase receptors, and nuclear receptors. The three former forms of receptors are membrane-bound proteins with both extracellular and intracellular domains. Alternatively, the gaseous neurotransmitters do not bind to receptors per se but rather act directly to alter the activity of target proteins, such as guanylyl cyclase in the target neuron [11]. Therefore, not all chemical signals need to act on typical “receptor” proteins.

The extracellular domains of membrane-bound receptors contain the motifs to which neurotransmitters bind in order to achieve a conformational change in the protein. In the case of ionotropic receptors, the resulting conformational change in the receptor leads to the opening of a central pore that permits the movement of cations or anions across the membrane, resulting in rapid membrane depolarization or hyperpolarization [6]. These ionotropic receptors are typically heteropentameric receptor complexes that constitute combinations of potentially large families of receptor subunits (at least 16 genes encode subunits for glutamate ionotropic receptors; at least 12 genes encode subunits for ionotropic acetylcholine receptors; etc. [6]). Ionotropic receptor subunits typically each confer a unique set of properties (neurotransmitter binding pocket, selectivity of ion permeability, allosteric regulatory sites, etc.) to the mature protein, which allows for variability in the properties of these receptors.

G-protein-coupled, seven-transmembrane-spanning domain proteins represent the most common form of receptors for intercellular signals. More than 350 separate genes in the human genome encode ligand-gated G-protein-coupled receptors [19], representing a major superfamily of proteins mediating intercellular signaling. These receptors exert their intracellular effects through activation of heterotrimeric guanosine triphosphate (GTP) binding (G) proteins; there are 35 separate genes in the human genome encoding the various subunit proteins that can enter into these heterotrimeric complexes. In total, there are four major families of complexes: the $G_{s/olf}$, $G_{i/o}$, $G_{q/11}$ and $G_{12/13}$ families [20, 21]. Each family produces a different subset of intracellular biochemical events, ranging from alterations in ion channel function to regulation of lipase activity to the mobilization of kinases and phosphatases. Importantly, transmitter-dependent activation of ionotropic receptors and associated membrane currents (see above) are subject to modification by intracellular signaling

Figure 2.3 Receptors. Four major types of receptors, located pre- and postsynaptically, mediate neurotransmitter effects. These include ligand-gated ion channels (ionotropic receptors), G-protein-coupled proteins (metabotropic receptors), tyrosine kinase receptors, and intracellular nuclear receptors.

pathways, mostly through phosphorylation of the intracellular domains of the receptors or through direct gating by G proteins.

Nuclear receptors represent the signal by which steroid hormones achieve their physiological effects on cells [22]. Steroids, such as cortisol, estrogen, and allopregalone, can pass directly across cell membranes and reach their target receptors which are located within the cytoplasm. These receptors are typically immobilized by heat-shock proteins when not activated by their ligands. The interaction of the ligand with its receptor leads to a dissociation of the heat-shock protein, which in turn permits the movement of the receptor complex to the nucleus. In the nucleus, these

receptors act as transcription factors that can positively or negatively regulate gene transcription.

The final major family of receptors are the tyrosine kinase receptors [23]. These are transmembrane-spanning domain proteins that are capable of dimerization and autophosphorylation subsequent to binding by its endogenous substrates (which are typically the neurotrophins and growth hormones). Once phosphorylation of the dimer has occurred, the tyrosine kinase receptors are able to engage in protein–protein interactions that mediate their intracellular effects, such as the activation of Ras, phosphatidylinositol-3-kinase or phospholipase C.

These four major types of receptors allow for a diverse range of intracellular effects of released chemical signals. Because of the diversity of receptor types, intercellular signaling is capable of eliciting rapid changes in membrane polarization, mobilizing changes in intracellular kinase/phosphatase function, and directly affecting gene expression.

2.6 PRESYNAPTIC RECEPTORS

Most axonal terminals express receptors either for their own chemical transmitter (so-called autoreceptors; Fig. 2.3) or for the transmitter that is being released by another, nearby terminal (heteroreceptors; Fig. 2.3); these modes of transmission roughly equate to autocrine and paracrine signaling, respectively [2].

Simply, these presynaptic autoreceptors allow the releasing terminal to regulate the magnitude of its synthesis and release in a manner that stabilizes synaptic concentrations of the neurochemical within a narrow range. Therefore, these presynaptic receptors can be generally thought of as a mechanism by which feedback inhibition on neurotransmitter release is exerted by a variety of synaptically located chemical substances.

Autoreceptors typically mediate feedback inhibition on synthesis and release through a $G_{i/o}$ -coupled receptor. The binding of transmitter to the autoreceptor can produce a mobilization of $G_{i/o}$ protein activity, which in turn can activate G-protein-coupled inward-rectifying K^+ channels (GiRKs), leading to presynaptic terminal hyperpolarization [6]. Through this mechanism, increasing synaptic concentrations of transmitter translate into decreased probabilities of subsequent synaptic release events. These “release-regulating” autoreceptors represent a set of exciting targets that may represent novel methods for modulating neurotransmitter release by acting on the mechanisms designed to preserve homeostasis.

Additionally, presynaptic autoreceptors can modulate synthesis directly by decreasing cAMP concentrations and, in turn, PKA-dependent phosphorylation of the enzymatic biosynthetic machinery [2]. For example, in the dopaminergic system, cessation of dopamine release is accompanied by a dramatic increase in catecholamine synthesis that is secondary to reduced activation of presynaptic autoreceptors [24, 25]. In principle, the increase in synthetic capacity is designed to ensure that the reduction in release is not secondary to a depletion of transmitter reserve.

Other terminals may also regulate presynaptic function by releasing molecules that act on heteroreceptors. Many of these receptors (both ionotropic and metabotropic) may act to cause depolarization or hyperpolarization of the terminal, to affect phosphorylation of synthetic enzymes and/or of synaptic release elements, and so on. For example, excitatory presynaptic ionotropic acetylcholine receptors are expressed

by glutamatergic terminals, leading to a powerful control of glutamate secretion by acetylcholine [26, 27]; additionally, many of the typical autoreceptor proteins act as heteroreceptors by governing GiRK function on nearby terminals through heterosynaptic mechanisms. An increasing number of diverse mechanisms of presynaptic release modulation are becoming apparent.

2.7 TRANSMITTER INACTIVATION

Inactivation of released neurotransmitter is typically accomplished by active enzymatic biotransformation of the active signaling molecule and/or by internalization of the neurotransmitter via membrane-bound transporter proteins (Fig. 2.4). Pre- and postsynaptic neurons, as well as adjacent glial cells, are each participants in the processes of transmitter inactivation.

Intracellular uptake (internalization) of the transmitter, usually through a set of homologous 12-transmembrane-spanning domain proteins called plasma membrane transporters [28], is one mode of neurotransmitter inactivation. These transporters can be expressed by either the releasing entity or the glial cells that surround the synapse. There are molecularly unique transporter proteins that correspond to each of the major classical neurotransmitters; in fact, some transmitters (e.g., glutamate) can be taken up by multiple transporter proteins. Therefore, there is a sizable gene family that encodes for the membrane transporters.

Acetylcholine and the monoamines are largely reuptaken by the terminals that released the chemicals, while GABA, glutamate, and other amino acids are taken up by surrounding glial cells. This uptake process is sensitive to the concentration gradient of the neurotransmitter and to the availability of Na^+ . It is worth noting that these transporters may directly internalize the released chemical and/or may target a biotransformed product of the molecule because some transmitters are enzymatically modified prior to reuptake [2].

Neurotransmitters can be enzymatically biotransformed into molecules inactive at synaptic receptors, and this conversion can happen within the synapse or after internalization via a transporter (Fig. 2.4). The fate of the molecules, once biotransformed, can vary. In some cases (e.g., serotonin), neurotransmitters are catabolized into molecules that are then excreted [2]; in other words, the molecules do not reenter the neurotransmitter utilization pathways. In other cases, however, the neurotransmitter is converted into a molecule that can reenter the biosynthesis pathway. For example, acetylcholine, GABA, and glutamate are transformed either directly or through successive steps into their own precursor molecules (choline, glutamate, and glutamine, respectively), enabling the process of recycling [6]. Yet other molecules, such as peptide transmitters and growth hormones, are subjected to proteolysis in the synapse in order to eliminate or alter their further physiological effects.

For virtually all the classical neurotransmitters, a combination of biotransformation and reuptake is typical [2]. For example, GABA is taken up by glial cells and enters the “GABA shunt”, which involves successive deamination of GABA to succinic semialdehyde and amination of α -ketoglutarate to glutamate, which can then be transported back to the releasing presynaptic terminal for further synthesis of GABA [6]. On the other hand, serotonin is largely taken up by the serotonin transporter, followed by successive oxidation and dehydrogenation [3].

Figure 2.4 Transmitter inactivation. The inactivation of neurotransmitter typically involves reuptake and/or further biotransformation. In some cases, reuptake is into the presynaptic terminal, while in others it can be into surrounding glial cells. Biotransformation can involve the generation of a product that can reenter the biosynthesis pathway (recycling) or of an inactive molecule (catabolism).

Other chemical signals, such as the gaseous neurotransmitters, have no known inactivation mechanism [11]. The end of their physiological effects may depend simply on diffusion along their concentration gradient, away from the site of release and target action. It is notable that the lack of inactivation mechanisms technically violates the criteria for a neurotransmitter described above in Section 2.1. Obviously, the discovery of new chemical signaling molecules may require a progressive refinement of the “rules” of chemical signaling.

2.8 TWO PROTOTYPIC NEUROTRANSMITTERS: GLUTAMATE AND DOPAMINE

The previous sections outlined the general principles by which intercellular signaling is generally accomplished in the nervous system. Here, two classical transmitters,

glutamate and dopamine, will be described in greater detail in order to more fully illustrate the usual mechanisms for intercellular signaling in the brain.

2.8.1 Glutamate

Although glutamate is a common amino acid that participates in various aspects of intermediary metabolism in neurons (including as a precursor for another neurotransmitter, GABA), it also is a key excitatory amino acid neurotransmitter belonging the group of classical signaling molecules described above (Table 2.1). Despite the prevalence of glutamate and its functions, the neurotransmitter pool of glutamate is regulated according to the general principles described in the preceding sections. Figure 2.5 illustrates the mechanisms governing glutamate synthesis, packaging, release, receptor action, and inactivation.

As the principal excitatory neurotransmitter in brain, glutamate is synthesized and released by neurons whose cell bodies are found throughout the central nervous system. In these neurons, the neurotransmitter pool of L-glutamate is biosynthesized from the precursor glutamine by the enzyme glutaminase (Table 2.2, Fig. 2.5). Alternative pathways are possible, including the transamination of α -oxoglutarate [2]. Cytosolic synthesis of glutamate is followed by its packaging into vesicles via a set of vesicular glutamate transporters consisting of at least three separate gene products (vGluT1–3; [29]). The intravesicular transport of glutamate, which is stereoselective, is dependent upon the electrochemical gradient across the vesicular membrane. The filled vesicles are subsequently docked, primed, and exocytosed in response to action potential-dependent increases in cytosolic Ca^{2+} .

Once released into the synapse, glutamate is free to act on both ionotropic and metabotropic receptors, located both pre- and postsynaptically. These include the ligand-gated ion channels, termed *N*-methyl-D-aspartate (NMDA)-sensitive, kainate-sensitive, and α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)-sensitive glutamate receptors. Each is a glutamate-regulated, heteropentameric cation channel that is constructed from combinations of subunit proteins drawn from a family of at least 14 gene products: GluR1–7, KA1–2, NR1 and 2A–D [30]. Without a doubt, these various subunits confer individual properties to the mature subunit complex (allosteric binding sites, additional kinetic properties, etc.), so although there are three general types of ionotropic glutamate receptors (NMDA, AMPA, kainate), there may be additional diversity within each class related to subunit composition.

An additional set of at least eight gene products makes up the metabotropic G-protein-coupled glutamate receptors (mGluR1–8; [31]). This group of receptors largely signals intracellularly through either G_i (mGluR2–4,6–8) or G_q (mGluR1,5) pathways. It is the mGluR2–3 receptors that constitute the presynaptic autoreceptor for the glutamate system [32, 33], exerting feedback inhibition on glutamate release and synthesis.

After receptor activation, glutamate is inactivated by uptake, either into the presynaptic terminal or (more generally) into glia. In brain, the uptake of glutamate into glia occurs via an excitatory amino acid transporter (EAAT), specifically EAAT1 and EAAT2. Subsequent conversion of glutamate to glutamine by glutamine synthetase is followed by recycling of glutamine back to the releasing terminal for subsequent entry into the biosynthetic pathway.

Figure 2.5 Biochemical mechanisms for glutamate synthesis, release, and disposition. Glu: glutamate; VGLUT: vesicular glutamate transporter; EAAT: excitatory amino acid transporter; MGluR: metabotropic glutamate receptor; NMDA: *N*-methyl-D-aspartate/glutamate receptor; AMPA: α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid/glutamate receptor.

2.8.2 Dopamine

Dopamine is a catecholamine transmitter that belongs to the group of biogenic amine molecules (Table 2.1). The neurons that make and release dopamine have cell bodies localized chiefly in the medulla, ventral mesencephalon, and hypothalamus. Figure 2.6 illustrates the biochemical mechanisms found at the synaptic terminals of these dopamine-releasing neurons that contribute to synthesis, packaging, release, post-synaptic actions, and inactivation.

Dopamine is synthesized via subsequent hydroxylation and decarboxylation steps. Tyrosine is converted into L-DOPA by tyrosine hydroxylase, and L-DOPA is sequentially converted into dopamine by aromatic acid decarboxylase (Table 2.2, Fig. 2.6). Once synthesized, dopamine is sequestered via the action of a vesicular monoamine transporter protein that successfully moves dopamine into vesicles via the reverse transport of H^+ . As with glutamate, these vesicles are then prepared for Ca^{2+} -dependent exocytosis.

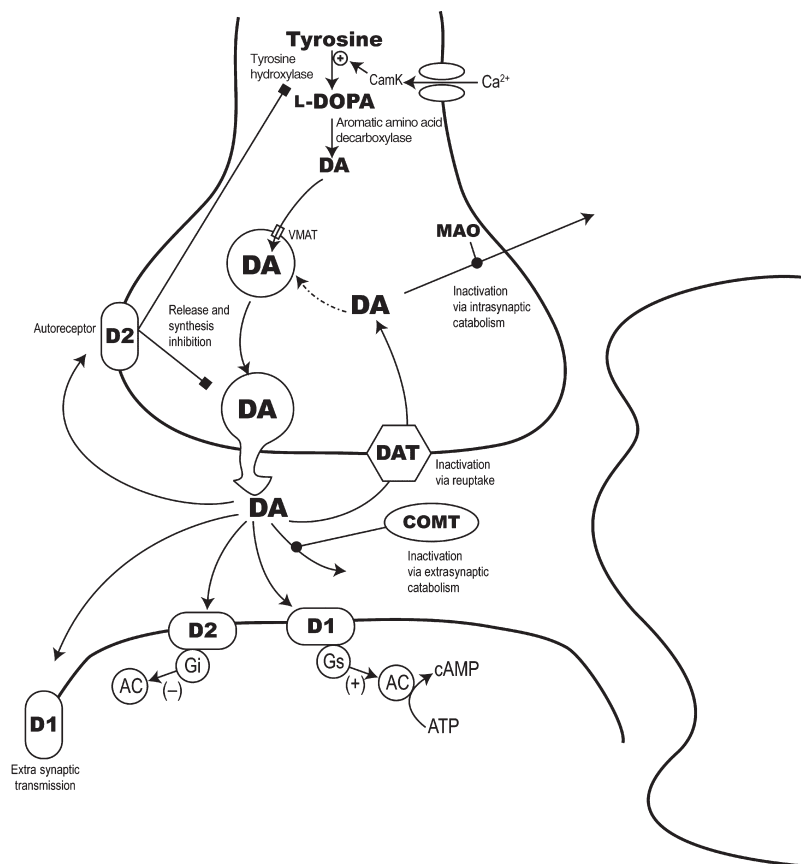

Figure 2.6 Biochemical mechanisms for dopamine synthesis, release, and disposition. DA: dopamine; VMAT: vesicular monoamine transporter; MAO: monoamine oxidase; COMT: catechol-*O*-methyltransferase; CamK: CaMKinaseII; DAT: dopamine transporter; AC: adenylyl cyclase.

Once released, dopamine acts on a set of at least five metabotropic G-protein-coupled receptors that are located both pre- and postsynaptically [34]. This family of receptors (D₁–D₅) are the mechanisms for (1) dopamine-mediated cAMP formation and phosphoinositide hydrolysis (via coupling to G_s) or (2) dopamine-mediated reductions in cAMP, opening of GiRKs and inhibition of Ca²⁺ channels (via coupling to G_i). The D₁ and D₅ receptors perform the former action, while the D₂, D₃, and D₄ receptors contribute to the latter.

Disposition of dopamine occurs via a number of routes. First, extracellular catabolism by catechol-*O*-methyltransferase (into 3-methoxytyramine) can occur; this enzyme is thought to be expressed by glia or postsynaptic neurons [35], rather than by dopamine cells themselves. Second, reuptake via dopamine transporters, followed by oxidation and methylation, is a typical means, as indicated by the high levels of the corresponding catabolites dihydroxy-*O*-phenylacetic acid and homovanillic acid in rats and humans, respectively [3].

Notably, not all routes occur equally in all brain regions. In the prefrontal cortex, one target of innervation by the dopamine neurons of the ventral mesencephalon, the dopamine transporter exists at very low levels [36, 37], meaning reuptake via this transporter contributes only minimally to inactivation, while it plays a much larger role in other brain regions, such as in the striatum. In the prefrontal cortex, therefore, extracellular catabolism is a prominent mechanism for dopamine disposition.

A final point which bears discussion is the discovery that dopamine actually exhibits higher affinity for the norepinephrine transporter than does norepinephrine itself [2]. With minimal dopamine transporter available, the norepinephrine reuptake transporters may play a significant role in dopamine disposition, a hypothesis supported by the finding that norepinephrine transporter inhibitors elicit increased synaptic levels of dopamine in the prefrontal cortex [38]. Of even greater interest, norepinephrine transporter immunoreactive cells in the prefrontal cortex do not express considerable amounts of the enzymes required to synthesize dopamine [39, 40], which is a required precursor for norepinephrine. Therefore, it is possible that noradrenergic neurons, under some circumstances, utilize dopamine taken up from the extracellular space as a precursor to produce their own neurotransmitter. New discoveries such as this clearly require an expansion of the way we think about neurotransmitter function.

2.9 SUMMARY

Although the discovery of a general set of principles describing the life span of classical neurotransmitters has been helpful in characterizing their functions as well as the modes of actions of psychotropic drugs that alter these pathways, these principles have also kept us ignorant of the way that less conventional mechanisms of intercellular signaling work in the brain. For example, the “paradigm” of action potential-dependent vesicular release does not apply to the gaseous and lipid transmitters, and inactivation mechanisms vary considerably across neurotransmitters and brain regions. The discovery of novel transmitters also allows for the discovery of novel means of chemical signaling, and it is undoubtedly the case that many new mechanisms will be found in coming years.

In synaptic signaling, the response of an individual neuron is determined by its complement of receptors. As discussed in other chapters in this volume, ligand-gated ion channels mediate fast synaptic transmission between neurons. However, signaling within an individual neuron is mediated by a complex set of interactions that occur primarily as a result of G-protein-linked signal transduction. The beauty of this system is in its diversity and inherent capacity for amplification and plasticity in the modulation of many different cellular functions. The initial signal sequence in this type of signaling typically is the generation of a second messenger inside the cell that then in turn activates a number of different proteins capable of modifying cellular processes. This chapter will present examples and an in-depth discussion of these intracellular signaling pathways beginning with G-protein-linked signaling, perpetuated by G-protein-coupled receptor (GPCR) stimulation. Next, ion channel modulation via G proteins as well as direct GPCR interactions with the channels will be discussed. The long list of intracellular downstream effector pathways, including cyclic nucleotide signaling, protein kinase signaling, and calcium-regulated signaling, are also described. The final focus of the chapter is protein phosphorylation cascades, a predominant mechanism in many signal transduction schemes. It is through these complex interactions that an individual cell is able to respond to neurotransmitter stimulation and modify many of its cellular processes to contribute to the overall symphony of synaptic signaling.

3.1 G PROTEINS AS SIGNAL TRANSDUCERS

Classically, receptors bind neurotransmitter, hormone, or other ligands on their extracellular surface, thus causing a conformational change and transference of the ligand-encoded signal/message to the intracellular compartment for propagation. Many of these signal-transducing receptors belong to the GPCR superfamily. GPCRs consist of seven transmembrane-spanning α -helix bundles that snake through the plasma membrane. Mutagenesis and biochemical experiments suggest that ligand binding to the extracellular face of the GPCR changes the relative orientation of the transmembrane domains. This conformational change carries through to the intracellular loops and carboxyl terminus, thus unmasking protein interacting domains [1]. Importantly, among the protein interacting sites in this intracellular region are amino acid residues critical for the interaction with heterotrimeric guanosine triphosphate (GTP)-binding regulatory proteins, or G proteins.

3.1.1 Heterotrimeric G Proteins

G proteins consist of subunits designated α , β , and γ . Multiple isoforms, activating a variety of signaling pathways, have been discovered for each of these subunits (Table 3.1). At present, there are 23 known isoforms of the human α subunit. $G\alpha$ is localized to the plasma membrane via lipid modification, specifically myristoylation and palmitoylation [2]. These modifications assist not only with membrane trafficking of the protein but also with membrane anchoring and interactions with $G\beta\gamma$ and downstream effectors [3, 4]. The $G\alpha$ subunit is a “flexible” protein consisting of two distinct domains—a Ras-like GTPase region and a helical domain. Together, these domains form the binding pocket for GTP and guanosine diphosphate (GDP) [2].

TABLE 3.1 G-Protein Subtypes

G-Protein Family	Subtype	Consequence ^a	Tissue Distribution	Comments ^b
G_{i/o}	G _{zs}	↑ Adenylyl cyclase	Ubiquitous	1

^acGMP = cyclic adenosine monophosphate; PDE = phosphodiesterase.^b(1) Cholera toxin Activation. (2) Pertussis toxin inhibition. (3) Pertussis toxin insensitive.

There are 6 known human isoforms of G_β and 12 of G_γ; these subunits also contain lipid modifications for membrane targeting [5]. With relatively few exceptions, most β and γ isoforms can form functional heterodimers, together forming a structure consisting of a β propeller and an α-helical region that is far more rigid than the G_α subunit [6]. There is currently much interest in the importance of specific G_{βγ} dimers utilized within individual signaling pathways. The possibility of differential association of the α subunit with these βγ dimers adds another level of complexity to the generation of signals downstream of activated GPCRs.

The activated receptor interacts with the inactive, GDP-bound form of the heterotrimeric G protein to form the RG complex, thus inducing GDP release from the G protein and beginning the G-protein activation cycle (Fig. 3.1 [7]). It is hypothesized that the receptor–G protein contact sites are separated from the G-protein GDP binding pocket, so that the receptor must “work at a distance” to change the G-protein conformation and release the GDP [8]. Upon release of the GDP, a stable complex is formed between the receptor and heterotrimeric G protein; this complex is termed R*G. GTP then binds to the G protein, inducing a conformational change in the G_α subunit that leads to decreased affinity for the G_{βγ} subunits and the receptor. This conformational change also unmask a hydrophobic pocket on the G_α subunit that is the site of interaction with effector proteins [9]. The complex then dissociates from the receptor, releasing activated G_α–GTP and G_{βγ}, which can each interact with and regulate various multiple effector molecules before cessation of activity [7]. The G-protein signal is terminated by intrinsic hydrolysis activity of the G_α subunit, which converts the

Figure 3.1 Heterotrimeric G-protein activation/inactivation cycle. In the absence of agonist, the GPCR interacts with the GDP-bound form of the G protein. Following agonist binding, GDP is exchanged for GTP and the G protein dissociates from the receptor, separating into GTP-bound $G\alpha$ and $G\beta\gamma$ subunits. Each of these subunits is capable of stimulating effector proteins. After initiating downstream signaling cascades, the $G\alpha$ subunit is turned off via hydrolysis of GTP to GDP. The $G\beta\gamma$ subunit can then reassociate with the GDP-bound $G\alpha$ subunit, thus shutting off G-protein activity and enabling reassociation with the GPCR.

$G\alpha$ -bound GTP to GDP. Association of $G\alpha$ with GDP increases the affinity of $G\alpha$ for $G\beta\gamma$. The heterotrimeric G protein re-forms and is again able to interact with the receptor.

The downstream signaling targets of all four $G\alpha$ classes have been well established and are listed, along with expression profiles, in Table 3.1; these pathways will also be covered in greater detail in subsequent sections. Briefly, G_s and $G_{i/o}$ both modulate adenylyl cyclase (AC) to alter cyclic adenosine monophosphate (cAMP) levels and affect protein kinase A (PKA) activity. G_q proteins target the phosphoinositide pathway by increasing phospholipase C (PLC) activity, which causes downstream release of intracellular Ca^{2+} and activation of protein kinase C (PKC). Activation of $G_{12/13}$ causes stimulation of specific RhoGEF proteins, which can activate phospholipase D (PLD) and other effectors. It was once believed that $G\beta\gamma$ proteins functioned solely to hold $G\alpha$ subunits in an inactive state. However, it is now known that, upon dissociation from $G\alpha$, the $G\beta\gamma$ dimer is capable of activating effector proteins as well. The known downstream effectors of $G\beta\gamma$ are protein kinases, small G proteins, AC, and ion channels, including N and P/Q-type Ca^{2+} channels and G-protein-regulated inward-rectifier K^+ channels. Through the many isoforms and potential heterotrimer combinations, the ability of a single activated G-protein subunit to rapidly activate multiple downstream molecules, and the array of protein targets that can be affected by G proteins, it is not surprising that the consequences of GPCR activation within a cell are rapid and wide reaching. Moreover, because of the

many downstream consequences of G-protein signaling cascades, GPCRs have become a favorite target for drug development.

3.1.2 Small G Proteins

In addition to the heterotrimeric G proteins, there is also a superfamily of monomeric GTP binding proteins. The molecular weight of these small G proteins ranges from 20 to 40 kDa and they are subdivided into five families: Ras, Rho, Rab, Sar1/ADP ribosylation factors (ARF), and Ran. There is 30–50% homology across families and all members possess a G domain. The G domain consists of a combination of α helices and β sheets and is characterized by highly conserved loop regions that are responsible for guanine nucleotide recognition [10]. Small G proteins are activated by guanine nucleotide exchange factors (GEFs, discussed in greater detail below) to exchange GDP for GTP. Binding of GTP stabilizes the switch regions, which are critical for recognition and activation of downstream effectors. Following effector activation, the very low intrinsic GTPase activity of the small G protein is enhanced by accessory proteins and GTP is hydrolyzed to GDP, resulting in a loss of activity and a return to the GDP-bound inactive state.

The downstream effector targets of small G proteins are quite different across the superfamily. The Ras family is best known for activation of mitogen-activated protein kinase (MAPK) and its transcription factors. This pathway is initiated following ligand stimulation of receptor protein tyrosine kinases; Ras is directly activated by the GEF son-of-sevenless (Sos), and the downstream signal proceeds through the Raf/MAPK/ERK (extracellular signal-related protein kinase) cascade. Recently, the Ras family has been shown to activate other effectors as well, including p120GAP and phosphatidylinositol 3-kinase. All of these effector proteins have roles in the regulation of cell growth, morphology, and apoptosis [11]. The Rho family of small G proteins are activated by interaction with GEFs, including Dbl and Vav, and are responsible for control of the actin cytoskeleton. The members of the Rho family accomplish this task by stimulating a variety of effectors, including the well-described c-Jun N-terminal kinase (JNK) pathway and activation of p160MAPK [12]. The ARF family proteins are best known as ribosylation factors and assist in the cholera toxin-mediated adenosine diphosphate (ADP) ribosylation of the heterotrimeric G_s protein. There are many different GEFs for the ARF family, including ARF nucleotide binding site opener (ARNO) and the cytohesins [13]. The fourth family of small G proteins, the Rab proteins, are localized to distinct cellular compartments and regulate secretory and endocytic pathways. Rabs facilitate the formation of SNARE (soluble N-ethylmaleimide-sensitive fusion protein attachment protein receptor) complexes. For this purpose, the Rab proteins must be held in the GTP-bound form for prolonged periods; this task is accomplished by the Rab binding proteins, including Rabphilin and Rabaptin [14]. The final family, the Ran G proteins, are activated by GEFs such as RCC1 that are localized in or near the nucleus. This positioning of Ran and its GEFs is critical for the consequence of Ran activation—trafficking of protein and RNA in and out of the nucleus [15].

In addition to the pathways detailed here for activation of small G proteins, there is also crosstalk between these protein pathways and the signaling cascades of heterotrimeric G proteins, including downstream of G_i and G_{13} activation. Following ligand-stimulated activation and separation of the G_i heterotrimer, the $G\beta\gamma$

dimer can stimulate effector proteins. It has been demonstrated that $G\beta\gamma$ released from G_i can activate Src, which is upstream of Ras in the MAPK signaling pathway [16]. Among its other effector proteins, $G\alpha_{13}$ can bind to and activate p115RhoGEF, which directly activates Rho and its downstream signaling cascade [17]. For a few small G proteins, direct interaction with the intracellular face of a GPCR has been demonstrated, including the interaction of ARF with the M3 muscarinic receptor [18, 19]. It is not presently known if the ultimate consequence of this mechanism of small G protein activation is identical to activation through “traditional” GEFs, or if this GPCR–monomeric G protein interaction may be part of a distinct and unique cellular signaling pathway.

3.1.3 Regulation of G-Protein Cycle

For both heterotrimeric and small G proteins, regulation of GDP–GTP exchange and GTP hydrolysis is critical in controlling the initiation and duration of the G-protein signal and, consequently, the cellular response to that signal. As such, tight control of the G-protein activation cycle occurs through an array of interacting proteins. While in the GDP-bound, inactive state, small G proteins interact with accessory proteins termed GDP dissociation inhibitors (GDIs). To date, GDIs have been described for Rho and Rab. In addition to stabilizing the small G protein in its inactive, GDP-bound form, GDIs also extract GDP-bound small G proteins from the membrane and partition them in the cytosol [10].

To initiate G-protein activity, GDP must be replaced by GTP. The GDP–GTP exchange process is rate limiting in the G protein cycle and must be catalyzed for efficiency; this exchange occurs with the aid of GEFs. For heterotrimeric G proteins, the ligand-bound GPCR acts as a GEF, facilitating a conformational change in the G protein that favors exchange of GDP for GTP. For the small G proteins many distinct GEF proteins exist to accomplish this task; several of these GEFs were discussed in the context of small-G-protein activation. Similar to GPCR activation of heterotrimeric G proteins, GEFs for small G proteins are typically activated by an extracellular signal, often transduced through a receptor tyrosine kinase. GEFs are necessary to expedite the otherwise inefficient guanine nucleotide exchange process. More recently, another class of proteins termed GDP dissociation stimulators (GDSs) have been identified. The consequence of small G proteins interacting with GDSs is quite similar to the effect of GEFs, but GDS proteins have been demonstrated to lack the substrate specificity that GEFs display [20].

Once GTP is bound, the G protein is activated and may stimulate multiple effectors and/or each effector protein multiple times. While this rapid and prolific propagation of the signal is necessary, it must not remain unchecked. It has already been mentioned that small G proteins and $G\alpha$ subunits contain intrinsic GTPase activity. However, this low level of activity requires stimulation in order to be effective in signal termination. A variety of GTPase-activating proteins (GAPs) increase the rate of hydrolysis of GTP to GDP. For the heterotrimeric G proteins, many of the downstream effector targets of $G\alpha$ actually serve as GAPs, including adenylyl cyclase [21] and $PLC\beta$ [22]. In addition to these GAPs, recently identified regulators of G-protein signaling, or RGS proteins, also expedite the hydrolysis of GTP to GDP. These proteins are classified into six subfamilies based upon alignment

of their RGS domains and similarities in sequence/structure of flanking regions. Unlike the GAPs for small G proteins, the heterotrimeric RGS G proteins do not actively hydrolyze the bound GTP. Rather, they stabilize the $G\alpha$ subunit in a conformation that allows most efficient activity of the endogenous $G\alpha$ GTPase activity [23]. There is evidence from RNAi studies that RGS proteins can work in a receptor-specific manner, targeting $G\alpha$ subunits downstream of activated M3 or AT1a receptors [24, 25]. These RGS proteins may be activated by directly interacting with the specific GPCR to target $G\alpha$. In contrast to $G\alpha$ subunits, small G proteins have extremely low levels of endogenous GTPase activity and lack an Arg residue that is critical for GTP hydrolysis. Because of this, small G proteins require specialized GAPs that actively contribute to hydrolysis; proteins that can serve this function include the Ras GAP p120 and the Rho GAP p190 [11].

3.1.4 Alternate Roles for RGS Proteins

The role for RGS proteins as signal terminators has recently been expanded to include an ability to function as signal modulators and signal integrators. It has been determined that overexpressed RGS4 can effectively block/terminate G_q - and $G_{i/o}$ -mediated signaling cascades. However, when low levels of RGS4 are expressed in cells, the G_q -directed Ca^{2+} signal is not blocked, but instead a rhythmic, oscillatory Ca^{2+} response is observed [26]. This finding suggests that the complete blockade of G-protein-mediated response occurring when RGS proteins are overexpressed may be, in part, an artifact of overexpression. Physiological levels of RGS proteins are quite low in comparison, and the RGS proteins likely serve multiple functions in vivo, including but not limited to signal termination. Furthermore, while the mechanism governing this novel RGS function has not been determined, it is quite possible that the RGS proteins are acting as scaffolding proteins at the plasma membrane, assembling G proteins and their related signaling machinery into a complex, thereby enabling alternate and/or modified cell signals [26, 27].

The fact that many RGS proteins have numerous protein–protein interaction motifs, including PDZ binding motifs, pleckstrin homology, GGL ($G\gamma$ -like) and PDZ domains, provides further support to the hypothesis that RGS proteins can bring together multiple proteins and potentially act as scaffolds. One example of a direct protein–protein interaction involving RGS has been demonstrated between the R7 subfamily of RGS proteins and the $G\beta 5$ subunit [25–29]. In this dimer, the RGS protein substitutes for $G\gamma$ via its GGL interaction domain. The membrane-bound fraction of this dimer may actually associate with $G\alpha$ subunits, substituting for $G\beta\gamma$ and coupling inactive $G\alpha$ –GDP to GPCRs [25, 28], while the cytosolic fraction may merely serve to prevent recoupling with $G\alpha$, or possibly even participate in another signaling cascade through its documented interaction with the scaffolding protein 14-3-3 [26, 30].

RGS proteins can also provide links between heterotrimeric and monomeric G-protein signaling cascades. The RGS protein p115-RhoGEF is activated downstream of $G\alpha_{13}$ –GTP; p115-RhoGEF then activates the Rho signaling cascade. Interestingly, not only is p115 a GEF for Rho, it also possesses potent GAP activity for $G\alpha_{12/13}$ subunits; thus it is able to negatively regulate the very protein that caused its activation. In addition to p115RhoGEF, G-protein receptor kinases (GRKs) are RGS proteins that also have multiple interacting partners and well-described cellular

roles apart from their RGS/GTPase function. GRKs are perhaps best known for their role in receptor phosphorylation/desensitization; however, they also possess a low level of RGS activity, further contributing to their ability to turn off specific G-protein signals.

3.1.5 G Proteins and Disease

While the downstream signals from G proteins are critical for proper cell regulation, response, and survival, these signals can also be detrimental for the cell if left unregulated. In a variety of tumors, this is precisely what occurs. Small G proteins have many well-documented oncogenic mutations, including mutations that prevent GTP hydrolysis, leaving the G protein permanently in the “on” state and mutations that enhance GDP–GTP exchange, promoting an active state of the G protein [31, 32]. This constant signal results in unchecked cell growth and abnormal cell cycle progression and migration. Not only do these oncogenic mutations cause tumor initiation, but they may also contribute to tumor invasion and metastasis [33].

Mutations within the genes encoding $G\alpha$ are rare and lead to distinct disorders. A mutation resulting in a gain-of-function (or permanent on state) in the $G\alpha_s$ protein leads to the endocrine disorder McCune–Albright syndrome [34, 35]. Loss-of-function mutations in $G\alpha_s$ are also disease-causing, as evidenced by the congenital syndrome Albright hereditary osteodystrophy. This disorder is caused by a partial loss of $G\alpha_s$ function, termed haploinsufficiency [34, 35]. G proteins can also be targeted for modification by bacterial toxins; this is the mechanism of action of both cholera and pertussis toxin. Cholera toxin inhibits hydrolysis of GTP from $G\alpha_s$ –GTP, thus leaving the G protein in an active state, while pertussis toxin ribosylates the $G_{i/o}$ heterotrimer, preventing activation of the G protein. The importance of G proteins in cellular communication and regulation is underscored by the deleterious effects caused by mutations and posttranslational modifications of these proteins.

In addition to the diseases described here, it is quite likely that dysfunction of monomeric and heterotrimeric G proteins contributes to many polygenic disorders with undefined etiology. While much is already known about G proteins, there are still obvious gaps in our knowledge, and new discoveries in the field alter how we perceive cellular signaling mechanisms and interactions. By further expanding our knowledge of G-protein structure, function, and activation/deactivation, we can move closer toward understanding the importance of these proteins not only in normal cellular function but also in diseased conditions. This knowledge could enable the development of therapeutics that target G proteins as well as their activators and effectors, yielding novel disease treatments.

3.2 GPCR–G PROTEIN MODULATION OF ION CHANNELS

Communication between neurons across synapses requires the release of presynaptic neurotransmitters and postsynaptic receptor activation. This synaptic transmission in the nervous system has long been known to be mediated by ion channels, which, when activated by a transmitter, allow charged ions to pass through the opened channels resulting in a change of potential across the postsynaptic cell membrane. GPCRs, which are directly coupled not to ion channels but to G proteins, as

discussed in earlier sections, were once generally thought not to play a predominant role in synaptic fast (ionotropic) transmission. However, evidence now supports an indispensable role for GPCRs in controlling the efficacy of this transmission by modulating the function of ligand-gated ion channels. Furthermore, GPCRs also mediate slow synaptic transmission via regulation of voltage-gated calcium and potassium ion channels as well as through their more well known role of generating second messengers.

GPCRs are able to influence ion channels through two distinct mechanisms. One involves the modulation of ion channels by diffusible second messengers either through G proteins or through downstream signaling molecules such as cAMP, PKA, or PKC. The second is through direct protein–protein interactions between ion channels and GPCRs. The latter mechanism is less understood even though it allows for a more specific form of regulation. Both G-protein- and second-messenger-mediated regulation of ion channels as well as direct GPCR-ion channel interactions will be reviewed.

3.2.1 $G\beta\gamma$ Signaling to Ion Channels

Modulation of ion channels by diffusible G proteins can be both indirect (via stimulation of second messengers) and direct (via physical interactions between G-protein subunits and the channel protein). The most intensely studied directly interacting G protein with ion channels is the $G\beta\gamma$ dimer. As discussed above, after activation of the GPCR, conformational changes in the $G\alpha\beta\gamma$ heterotrimer facilitate the exchange of GDP for GTP on the α subunit and the ensuing dissociation of $G\beta\gamma$ from $G\alpha$. The GTPase activity of the $G\alpha$ subunit reverses this process [36]. It is during this stimulation and subsequent dissociation that $G\beta\gamma$ is free to activate a large number of effectors. The most intensely studied and best understood example of ion channel regulation by $G\beta\gamma$ is the G-protein-activated inwardly rectifying K^+ (GIRK) channel [37, 38]. GIRK channels are expressed in the heart, central and peripheral nervous systems, and endocrine system where they control postsynaptic inhibitory signaling and hormone secretion [39]. In the central nervous system (CNS), activation of GIRK channels mediates the inhibitory actions of γ -aminobutyric acid (GABA), acetylcholine, adenosine, somatostatin, and opioids. The clinical importance for GIRK channels in the CNS has been elucidated via use of the compound flupirtine, a centrally acting nonopioid analgesic that activates pertussis toxin-sensitive GIRK channels, leading to an indirect inhibition of *N*-methyl-D-aspartate (NMDA) receptor activity [40]. Studies with this compound have shown that it protects neurons from the toxic effects of prion proteins, amyloid- β and glutamate. These data suggest that activation of GIRK channels may be of therapeutic value and a target for the treatment of neurodegenerative disorders [41].

The regulation of GIRK channels proceeds as follows: the $G\beta\gamma$ protein directly binds to and activates the channel [42]. This creates a linking mechanism between GPCR activation and the regulation of ion channel function. The precise mechanism of how a diffusible protein ($G\beta\gamma$) is able to activate the GIRK is beginning to be unraveled. Specific amino acids in the channel pore that when mutated render the channel both constitutively active and insensitive to $G\beta\gamma$ activation have suggested that $G\beta\gamma$ allosterically regulates the gating apparatus of the channel pore. $G\beta\gamma$ binds to the pore and likely causes a conformational rearrangement of the transmembrane

segment of the GIRK, capable of widening or narrowing the pore. The rearrangement is such that it results in GIRK channel activation [39]. Through this mechanism, GPCR activation of G_i proteins elicits profound effects on GIRK channel function (Fig. 3.2a) [43].

Importantly, it has been elucidated that GIRK channels are regulated by multiple mechanisms by GPCRs. In systems that contain both G_i -coupled GPCRs and G_q -coupled receptors, coactivation of the GPCRs results in competing effects on the GIRK. Simultaneous stimulation of both G_i - and G_q -coupled GPCRs activates GIRK initially through $G\beta\gamma$ as discussed above, but stimulation of PLC by $G\alpha_q$ reverses this activation. It does this by decreasing phosphatidylinositol-4,5-bisphosphate (PIP₂) and increasing diacylglycerol (DAG). DAG in turn recruits PKC, resulting in phosphorylation of the GIRK and subsequent decreased interaction between GIRK and PIP₂, resulting in channel inhibition (Fig. 3.2b). [43]. Therefore, different GPCRs are capable of regulating the same ion channels via different mechanisms, resulting in opposite functional outcomes.

GIRK channels are not the only ion channels modulated by diffusible $G\beta\gamma$ proteins generated through activation of GPCRs. Whereas GIRK channels are activated by GPCR-stimulated liberation of $G\beta\gamma$, voltage-gated Ca^{2+} channels (VGCCs) are inhibited. GPCR activation was first found to reduce action potential duration in dorsal root ganglion neurons in the 1970s. This observation was subsequently confirmed to be due to inhibition of VGCCs, and this effect has since

Figure 3.2 Modulation of GIRK channels by GPCRs. (a) Activation of GIRK channels by GPCR stimulation. Agonist binding to G_i -protein-coupled GPCR results in the liberation of $G\beta\gamma$, which in turn binds to the GIRK channel and activates it in the presence of PIP₂. (b) Inhibition of GIRK channels by GPCRs. Simultaneous stimulation of both G_i - and G_q -coupled GPCRs activates GIRK initially, but G_q stimulation of PLC decreases PIP₂ and increases diacylglycerol (DAG), which recruits PKC. Phosphorylation of GIRK subunits results in decreased interaction with $G\beta\gamma$ and PIP₂ and channel inhibition. Adapted from [43] with permission.

been observed in many types of neurons (for review, see [44]. VGCCs play a major role in the functioning of nearly all neurons and other excitable cells being crucial for depolarization and transmitter release [44]. Studies have revealed that $G\beta\gamma$ binding to VGCCs results in inhibition of the calcium current manifested by slowing of the current activation kinetics. GPCRs typically involved in this type of modulation include α_2 adrenoceptors, opioid receptors, and GABA-B receptors [44]. The mechanism behind this inhibition occurs through a series of convergent modifications in the biophysical properties of the channel. This likely involves the reluctance of VGCCs to open when they are bound to G proteins and may require that the $G\beta\gamma$ be dissociated before the channel is able to open normally (for review, see [45]). A simple model would be that on any given cell only the non- $G\beta\gamma$ -bound channels open while the bound ones do not, leading to an overall decrease in VGCC gating. This inhibition is fast and relieved by depolarization, likely through the dissociation of the G protein from the channel allowing for opening. In this way, GPCRs are able to regulate neurotransmission through the diffusible G protein $G\beta\gamma$ acting on VGCCs.

While extensive data have now demonstrated an indisputable role for $G\beta\gamma$ regulation of GIRK and VGCC, several other ion channels also have the potential to be regulated via this mechanism, including voltage-dependent K^+ channels [46], and adenosine triphosphate (ATP) sensitive K^+ channels [47]. Other, yet to be determined ion channels may show similar forms of regulation, indicating a more widespread effect of $G\beta\gamma$. Regardless of the channel affected, signaling through this mechanism is likely regulated in dynamic multi molecular complexes depending on cell type and localization of receptors in similar compartments allowing for selective signaling [48].

In addition to $G\beta\gamma$ binding directly to ion channels and modulating their opening, the heterodimer is also known to elicit responses on downstream signaling molecules such as kinases and small G proteins [2]. These downstream signaling molecules also have a vast potential to regulate ion channels, particularly through phosphorylation events. Additional downstream GPCR signaling molecule effects on ion channels will be discussed below.

3.2.2 Other Downstream Signaling Molecules That Modulate Ion Channels

As will be discussed in detail in subsequent sections, when GPCRs are activated, in addition to allowing for the dissociation of diffusible G proteins, they are further directly responsible for activating downstream signaling complexes such as cAMP, PKA, and PKC. Interestingly, these downstream signaling events are also capable of regulating ion channels in a variety of methods. These mechanisms increase the complexity of GPCR control on ion channels, allowing for more specificity of the interaction in controlling different receptors. This also allows for additional control of the ion channel by other factors that regulate these downstream signaling pathways. Perhaps surprisingly, multiple ion channels are regulated by both direct interactions with G proteins and indirectly via downstream signaling pathways, greatly increasing the crosstalk between GPCRs and ion channels.

Phosphorylation is a common mechanism for the modulation of ion channels, and this event is directed by kinases, some of which are stimulated via GPCR activation. Both voltage-gated and ligand-gated ion channels are regulated via phosphorylation controlling such events as receptor desensitization and activation [49]. VGCCs are

one example of a voltage-gated ion channel that is regulated by both mechanisms: $G\beta\gamma$ proteins and second-messenger protein kinases [50]. VGCCs are a substrate for phosphorylation by cAMP-dependent protein kinase [51]. In addition, modulation of calcium currents by PKC can occur through the initial activation of G_i or G_q resulting in the activation of PLC. In neurons, β -adrenergic and D_1/D_5 dopamine receptors can modulate some types of calcium channels through cAMP-dependent mechanisms. Some types of neuronal VGCCs are enhanced by activation of PKC, whereas other reports show that some types of VGCCs are inhibited by PKC. In addition, it has been shown that integration of GPCR signaling can take place by regulating the interaction of the VGCCs with different cellular proteins [50]. Taken together it is clear that multiple GPCR-mediated pathways converge to modulate ion channels in a variety of diffusible methods, including downstream regulators. The complex timing of events is controlled by interactions between components of multiple signaling pathways. These multiple mechanisms allow for the integration of a complex system where GPCR activation can modulate ion channels to control cellular transmission.

VGCCs represent just a single example of the many effects that downstream second-messenger signaling via kinases plays in phosphorylation and subsequent regulation of a number of ion channels. For example, stimulation of PKA by the D_1 dopamine receptor is able to affect voltage-gated K^+ channels, Na^+ channels, Ca^{2+} channels, NMDA receptors, α -amino-3-hydroxy-5-methyl-4-isoxazole propinoic acid (AMPA) receptors, and GABA receptors. To further complicate this regulation, PKC stimulation by this same GPCR (D_1 dopamine receptor) is capable of modifying some of the same channels, including Na^+ channels and Ca^{2+} channels [52]. Overall, it is easy to appreciate the complex regulation of ion channels by GPCR-stimulated protein kinases resulting in ion channel phosphorylation. With so many converging downstream regulators how can an individual cell determine which one is most influential? This is most likely a case of subcellular localization of the GPCRs and the affected ion channel; for example, when they are in the same cell type and in close proximity, they can affect each other. What actually occurs in vivo (the cumulative effect of multiple cellular systems eliciting control over the ion channel regulation) continues to be investigated.

3.2.3 Modulation of Ion Channels by Direct Protein–Protein Interactions with GPCRs

While we have discussed several means by which stimulation of GPCRs regulate the function and expression of ion channels, all of these were via indirect diffusible second-messenger-linked mechanisms. However, it is also becoming clear that GPCRs are able to regulate some ion channels through direct protein–protein interactions. While it is known that neurons contain many different types of GPCRs, they activate only a limited number of G-protein complexes and second-messenger pathways. Therefore, a potential challenge for the cellular regulation of ion channels by second-messenger molecules is regulating the high degree of selectivity and specificity that occurs inside any given cell. Some of these specificity issues may be addressed by direct protein–protein interactions between the GPCR and an ion channel. The direct protein–protein interactions appear to be functionally reciprocal in most cases,

allowing for the receptors to regulate each other. The majority of data examining this direct interaction involves ligand-gated ion channels interacting with GPCRs.

A growing body of evidence suggests that direct interaction of GPCRs and ligand-gated ion channels represents a mechanism by which two types of receptors work in concert to regulate synaptic transmission. One example of direct interactions between an ion channel and a GPCR is dopamine receptors interacting with GABA_A channels [53]. In this case the receptors comodulate each other, where activation of the GPCR (in this case D₅ dopamine receptor) inhibits GABA-mediated synaptic transmission and activation of the GABA receptor inhibits D₅ receptor-mediated cAMP accumulation. This reciprocal regulation is not via diffusible second messengers but by direct protein-protein interactions. The mechanism for this is likely cointernalization, where activation of one receptor initiates ligand-induced internalization and, because the two receptors are linked, internalizes the other receptor with it. While this mechanism is not entirely clear, it does highlight a mechanism by which GPCRs can modulate ion channels in a way that does not require diffusible second messengers.

The interaction of the D₁ dopamine receptor with glutamate receptors represents another complex regulatory paradigm where the ion channel is regulated via both diffusible second messengers and direct protein-protein interactions. D₁-like dopamine receptors enhance NMDA receptor-mediated responses by signal integration of cAMP response element binding (CREB) protein and PKA-dependent phosphorylation (for review, see [52]). Furthermore, D₁ receptor stimulation also enhances trafficking of the NMDA receptors and the GluR1 subunit of AMPA receptors [54, 55]. The GluR1 trafficking is mimicked by forskolin-induced activation of adenylyl cyclase and the NMDA receptor effect requires the Src family protein tyrosine kinases Fyn (for review, see [52]). Interestingly, the NMDA receptor is also regulated by direct protein-protein interactions with the C-terminus of the D₁ receptor, allowing the receptors to reciprocally regulate each other.

The direct protein-protein interactions between the D₁ receptor and the NMDA receptor is complex and results in multiple regulatory effects between the two receptors [56, 57]. The two receptors directly interact through not one but two distinct mechanisms—one with the C-terminus of the D₁ receptor and the NR1 subunit of the NMDA receptor and another between the C-terminus of the D₁ receptor and the NR2A subunit of the NMDA receptor [57]. Interestingly, it appears that these two distinct interaction sites mediate disparate functional consequences for GPCR-ion channel interactions. For the interaction with the NR2A subunit when the dopamine receptor is stimulated, the interaction results in inhibition of NMDA receptor-mediated ion currents. This effect is not due to any of the major signaling cascades known to be downstream of the D₁ dopamine receptor, since interference with PKA, PKC, and G proteins has no effect on this inhibition. Therefore, it is due to direct protein-protein-mediated changes in the receptor. In contrast, the other interaction (the one with the NR1 subunit) appears to be involved with another D₁-mediated effect, the suppression of NMDA receptor-mediated cell death [57]. This effect is not mediated by the inhibition of NMDA currents like that seen for the other interaction. Similar to the effects of D₁ stimulation on NMDA currents, this blockade of NMDA-mediated cell death does not involve G proteins. The precise mechanism of how these protein-protein interactions result in these functional effects remains unclear but may involve internalization of the ion channel following activation of the GPCR.

3.3 SIGNALING THROUGH CYCLIC NUCLEOTIDE SECOND MESSENGERS

GPCRs detect the presence of neurotransmitters, hormones, and other cellular activators by physically interacting with these signal-initiating molecules—the first messengers—and communicating their presence by activating intracellular heterotrimeric G proteins. Activated G proteins, in turn, modulate cellular effectors such as adenylyl cyclase (AC) that synthesize and regulate the amount of second messenger present inside the cell. The cyclic nucleotides adenosine 3',5'-monophosphate (cAMP) and guanosine 3',5'-monophosphate (cGMP) constitute the second messengers that are synthesized by the cellular effectors AC and GC. Once synthesized, second messengers go on to modulate a variety of cellular processes by activating protein kinases, gating ion channels, and modulating transcription factors to attune the cell's physiology in response to exposure to the first messengers—the culmination of the signal transduction cascade.

3.3.1 Adenylyl Cyclase

Adenylyl cyclase was the first cellular effector target identified for activated G protein. This observation led to the original hypothesis made by Sutherland and Rall that a single polypeptide could both recognize hormonal signals and synthesize adenosine-3',5'-monophosphate, that is, cAMP. We now know that cAMP production requires at least three proteins: (1) a membrane-bound receptor that recognizes and binds cognate agonist (first messenger) to activate associated (2) heterotrimeric G proteins that in turn bind and activate the (3) membrane-bound AC enzyme that catalyzes the transformation of ATP into cAMP. Figure 3.3 illustrates the prototypical hormone-sensitive AC signal transduction system.

Heterotrimeric G-protein regulation of AC activity is mediated by both the α and $\beta\gamma$ subunits. The α -subunit regulation of AC activity can be either stimulatory ($G\alpha_s$) or inhibitory ($G\alpha_i$) as is the $\beta\gamma$ -subunit regulation of AC activity. Table 3.2 summarizes the regulation of the various isoforms of AC by G protein. Hormonal activation of ACs is mediated predominantly by $G\alpha_s$ -coupled GPCRs, with $G\alpha_s$ being the most widely distributed activator of membrane-bound ACs in mammals [58]. Most of the focus of G-protein regulation of ACs was placed on the α subunits; however, $\beta\gamma$ dimers represent some of the most effective negative regulators of AC1 and AC8 [59]. Interestingly, the AC isoforms (AC2, AC4, and AC7) that are activated by $\beta\gamma$ dimers are not directly regulated by the α subunits of G_i proteins [58, 60]; thus, the modulation of AC activity by heterotrimeric G proteins is a complex process that exhibits AC isoform-specific regulation, providing a platform for crosstalk among different signal transduction systems.

Calcium ions represent an alternative modulator of AC activity that can also be either stimulatory or inhibitory. G proteins that do not directly bind AC can still modulate AC activity by gating ion channels that increase intracellular calcium ion concentration. AC1, AC3, and AC8 activity can be stimulated by Ca^{2+} in complex with the protein calmodulin [61, 62]. The mechanism via which Ca^{2+} /calmodulin (Ca^{2+} /CaM) activates AC depends on the particular isotype of AC. For example, activation of serotonin 5-HT_{7A} receptor stimulates AC8 activity, but this activation is mediated not by $G\alpha_s$ binding but by interaction of AC8 with Ca^{2+} /CaM [63]; thus,

Figure 3.3 Prototypical activation of adenylyl cyclase (AC). Hormone binds to a G α_s linked GPCR inducing the exchange of GDP for GTP on the G α subunit of associated heterotrimeric G protein, resulting in activation of G protein. Activated G α_s dissociates from the $\beta\gamma$ dimer and binds to and activates the catalytic region (C1–C2) of AC. AC is a single polypeptide that exhibits a bipartite arrangement of a six-transmembrane (TM) spanning region followed by an intracellular catalytic domain (C) configured into an intramolecular dimer. The linear domain arrangement of AC is depicted at the top as a horizontal bar diagram. The overall structure of AC resembles a membrane channel with both amino and carboxyl termini located within the cell as depicted by the bipartite barrel structure above. Activated AC synthesizes cAMP second messenger from cytosolic ATP, releasing pyrophosphate (PP_i). cAMP can go on to modulate the activity of a variety of cellular effectors, including cAMP-dependent PKA and cyclic nucleotide-gated channels (CNGCs), or be degraded by phosphodiesterase (PDE) resulting in attenuation cAMP signaling.

AC8 acts as a calcium ion detector with half-maximal stimulation achieved at 800 nM free Ca²⁺ [64]. AC1 is more sensitive to Ca²⁺ than AC8, achieving half-maximal activity at 150 nM of free Ca²⁺ [65]. Moreover, AC1 is also activated by G α_s . Activated G α_s and Ca²⁺/CaM synergistically stimulate AC1, causing AC1 to act as a coincidence detector to integrate increases in intracellular Ca²⁺ and activation of G α_s -GPCRs to enhance cAMP production [64]. Inhibition of AC, specifically AC5 and AC6, by Ca²⁺ does not require association with calmodulin and is mediated by both a low-affinity state that occurs in all tissues and a high-affinity state that occurs in select tissues, reviewed in [66]. Interestingly, calcium regulation of ACs is

dependent upon the method of how intracellular Ca^{2+} concentration is increased. An increase in intracellular calcium achieved by the opening of intracellular stores or by ionophore-mediated or arachidonic acid-mediated entry of external calcium through the plasma membrane does not alter AC activity, reviewed in [66]. Modulation of AC activity, especially the inhibition of AC5 and AC6, is linked to capacitative calcium entry (CCE)—the entry of calcium through the plasma membrane that is initiated upon depletion of intracellular stores, reviewed in [66, 67]. Transient receptor potential (TRP) channels are thought to be the plasma membrane channels that mediate the effective CCE current (reviewed in [68]).

Additional regulators of ACs that can be stimulatory or inhibitory include the protein phosphatase calcineurin and the following protein kinases: cAMP-dependent protein kinase (PKA, discussed below), PKC, and Ca^{2+} /CaM kinases (reviewed in [60, 69]). Several examples exist for inhibition of AC activity via direct phosphorylation by protein kinases. AC1 has been shown to be phosphorylated by CaM kinase IV *in vivo* and this phosphorylation results in a decrease in AC1 catalytic activity [70]. AC5 has been shown to be phosphorylated by PKA and this phosphorylation results in a decrease in the rate of AC5 generation of cAMP [71]. Interestingly, AC5 has also been shown to be phosphorylated by PKC α and PKC ζ at sites distinct from the PKA phosphorylation site, resulting in a 10- to 20- fold increase in AC5 catalytic activity [72].

Several chemical compounds have also been used to alter AC activity to examine the behavior of the enzyme under a variety of experimental conditions. All mammalian ACs are activated directly by the membrane-permeable diterpene forskolin, except for AC9 and the soluble form of AC (sAC). Use of forskolin alleviates the need for GPCR–G protein or calcium activation of AC to potentiate cAMP production. Conversely, P-site inhibitors have been used to inhibit AC activity in a manner that does not compete with ATP binding to the enzyme, reviewed in [58]. P-site inhibitors are mono- or polyphosphate structural analogs of cAMP. They inhibit AC activity by stabilizing the quasi-product-bound state. The capacity of P-site inhibitors to attenuate AC activity is dramatically increased by the presence of pyrophosphate.

Molecular cloning and expression experiments investigating sAC revealed that this isotype was insensitive to both G-protein and forskolin activation but highly sensitive to stimulation by bicarbonate ion [HCO_3^-] [73]. Several metabolic processes result in changes in the CO_2 content of cells. These changes are buffered when HCO_3^- , CO_2 , and H^+ reach equilibrium within the cell; hence, changes in energy usage as well as cellular pH would shift the concentration of reactants according to the buffering capacity of the reaction. Thus any changes that would increase HCO_3^- concentration would stimulate sAC to produce cAMP, making sAC a pH and CO_2 sensor within a cell [74]. Identification and characterization of sAC have forced a reexamination of how cAMP signals are propagated within the cell beyond activation of GPCRs at the plasma membrane [58].

Molecular cloning has identified a total of 10 isotypes of AC: 9 membrane-bound isoforms [58, 69] and sAC isoform [73]. The genes that correspond to the AC isoforms are distributed throughout the genome on multiple chromosomes, with the exception of AC7 [75] and AC9 [76], which are located on human chromosome 16, reviewed in [58]. Mammalian ACs are expressed in every tissue at very low levels; however, some isoforms are more ubiquitously expressed than others. AC1 and AC8

are expressed exclusively in neurons [61, 77] and are localized predominantly to regions in the brain associated with learning and memory. Table 3.2 summarizes tissue expression patterns of each AC isoform.

Combination of the molecular cloning sequence data with the information available on the modulation of the various AC isoforms enables the membrane-bound ACs to be grouped into three distinct families as follows: (1) Ca^{2+} /CaM-stimulated family that consists of AC1, AC3, and AC8; (2) the Ca^{2+} -insensitive, PKC- and $\text{G}\beta\gamma$ -stimulated family comprised of AC2, AC4, and AC7; and (3) the high-affinity Ca^{2+} - and $\text{G}\alpha_i$ -inhibited family comprised of AC5 and AC6 [58]. AC9 is the most divergent of the mammalian membrane ACs [78]. It is unique in that it is the only membrane-bound AC that is virtually insensitive to activation by forskolin. AC9 has been shown to be stimulated by $\text{G}\alpha_s$ [78, 79], and this stimulation is attenuated by activation of a novel PKC in HEK293 cells [79]. AC9 was found to be unresponsive to $\text{G}\beta\gamma$, Ca^{2+} , or Ca^{2+} /CaM treatment [78].

3.3.2 Cellular Targets of cAMP

Activation of AC by any of the methods discussed above results in the conversion of ATP into the second messenger cAMP and pyrophosphate. Conversely, cAMP can be hydrolyzed by enzymes known as phosphodiesterases (PDEs) to produce AMP and, hence, turn off cAMP signaling (Fig. 3.3). cAMP signaling is predominantly carried out by the binding of cAMP to and activation of the cAMP-dependent protein kinase (PKA).

PKA is a serine/threonine-directed kinase that exists as a tetrameric enzyme consisting of two regulatory subunits and two catalytic subunits. There are currently three catalytic subunits ($\text{C}\alpha$, $\text{C}\beta$, and $\text{C}\gamma$) and four regulatory subunits ($\text{RI}\alpha$, $\text{RI}\beta$, $\text{RII}\alpha$, and $\text{RII}\beta$) identified for PKA [80, 81]. It is the specific homo- and/or heterodimerization of the regulatory subunits that distinguishes the two forms of PKA holoenzyme: type I (consisting of RI subunits) is predominantly cytoplasmic and more sensitive to cAMP [82] and type II (consisting of RII subunits) is associated with specific cellular structures and organelles (reviewed in [83]). Each regulatory subunit consists of an N-terminal dimerization domain, an autophosphorylation site that binds the catalytic subunits, and two cAMP binding sites [84]. The regulatory domains of PKA serve two major functions: first, as an autoinhibitory module for the catalytic subunits in the absence of cAMP and, second, as a dimerization and docking domain (D/D domain) to localize the tetrameric holoenzyme to specific subcellular locations through association with A-kinase anchoring proteins (AKAPs) (reviewed in [85]). Upon synthesis, two molecules of cAMP bind to each regulatory subunit inducing activation and dissociation of the catalytic subunits from the regulatory subunits. The activated catalytic subunits are free to phosphorylate a diverse array of cellular substrates in both the cytoplasm and the nucleus. For example, phosphorylation of the transcription factor CREB in the nucleus by the catalytic subunits of PKA regulates gene transcription at CRE (cAMP response element) sites in promoter regions [86]. PKA can also phosphorylate PDE3A and PDE4, activating the enzymes to degrade cAMP, providing a negative-feedback loop to maintain levels of the second messenger in smooth muscle cells [87].

In addition to PKA, cAMP can also bind and regulate cyclic nucleotide-gated (CNG) channels in the cilia of olfactory sensory neurons [88] and cardiac pacemaker

TABLE 3.2 Regulatory Properties of Mammalian Adenylyl Cyclases

AC Isoform ^{a,b}	Tissue Distribution	Regulation by G-Protein Subunit	Protein Kinases	Calcium Effects	Putative Function
AC1	Brain adrenal medulla	Stimulated by $G\alpha_s$, Inhibited by $G\beta\gamma$, Inhibited by $G\alpha_0$	PKC: weak stimulation; CaMKIV: inhibition	Stimulated by Ca^{2+} -CaM inhibition	Learning, memory, LTP ^c , synaptic plasticity
AC2	Brain, skeletal muscle, lung, heart	Stimulated by $G\alpha_s$, Stimulated by $G\beta\gamma$ ^d	PKC: stimulation		
AC3	Brain, olfactory epithelium	Stimulated by $G\alpha_s$	PKC: weak stimulation; CaMKII: inhibition	Stimulated by Ca^{2+} -CaM	Olfaction
AC4	Brain, heart, kidney, liver, lung, BAT, uterus	Stimulated by $G\alpha_s$, Stimulated by $G\beta\gamma$ ^d	PKC: inhibition		
AC5	Heart, brain, kidney, liver, lung, uterus, adrenal, BAT ^c	Stimulated by $G\alpha_s$, Inhibited by $G\beta\gamma$ ^e , Inhibited by $G\alpha_s$	PKA: inhibition, PKC α,ζ : stimulation	Inhibited	
AC6	Ubiquitous	Stimulated by $G\alpha_s$, Inhibited by $G\beta\gamma$ ^e , Inhibited by $G\alpha_f$	PKA: inhibition; PKC: inhibition	Inhibited	
AC7	Ubiquitous, highly expressed in brain	Stimulated by $G\alpha_s$, Stimulated by $G\beta\gamma$ ^d	PKC: stimulation		Drug dependency

AC8	Brain, lung, testis, adrenal, uterus, heart	Stimulated by $G\alpha_s$	Stimulated by Ca^{2+} -CaM	Learning memory, LTP ^c , synaptic plasticity
AC9 ^g	Brain, skeletal muscle	Stimulated by $G\alpha_s$		
sAC ^h	Highly expressed in testes	Not regulated by G -protein subunits		Sperm capacitation

^aAll isoforms except sAC are inhibited by P-site inhibitors.

^bForskolin stimulates human AC1-8, whereas AC9 is weakly and sAC is not stimulated by forskolin.

^cBAT, brown adipose tissue; LTP, long-term potentiation.

^d $G\beta\gamma$ stimulation of AC is conditional upon $G\alpha_s$ co-activation.

^eInhibition determined by transfection and could be an indirect $G\beta\gamma$ effect.

^fDenotes $G\alpha_i$ family member $G\alpha_{i1}$, $G\alpha_{i2}$, $G\alpha_{i3}$ and $G\alpha_z$.

^gInhibited by calcineurin.

^hStimulated by bicarbonate.

channels in the sinoatrial node [89]. Both CNG channels are regulated by direct binding of cAMP. cAMP can also bind to EPAC—a chimeric protein comprised of a cAMP binding domain fused to a GEF domain that specifically activates the small G protein Rap1 of the Ras superfamily. Binding of cAMP to this GEF activates Rap1 in a PKA-independent manner [90].

3.3.3 Guanylyl Cyclase

Guanylyl cyclases (GCs) are the cellular effectors that synthesize the second messenger cGMP from GTP, reviewed in [91]. GCs are involved in physiological processes such as vision, bone growth, and vasodilation. GCs display a dramatically different structure from that of the ACs; however, there is considerable sequence similarity in the catalytic regions of each class of cyclase that produce the cyclic second messengers [92]. Mammalian GCs exist in two forms—membrane bound and soluble—as do the ACs. In contrast to the membrane-bound ACs, the membrane-bound GCs directly bind agonist to initiate cGMP production instead of activation via an agonist–GPCR–G protein avenue. Figure 3.4 depicts the domain structure of mammalian GCs.

Soluble GC (sGC) lacks the extracellular domain (ECD), the transmembrane (TM) domain, and the kinase homology domain (KHD) present in the membrane-bound analogues. Instead, the sGC contains an N-terminal heme domain that binds nitric oxide (NO)—the uncharged free-radical compound that stimulates cGMP production in this enzyme [93]. NO is produced from L-arginine by nitric oxide synthase (NOS) [94]. sGC exists as a heterodimer, with α_1/β_1 being the most abundant species. sGC regulates smooth muscle relaxation, platelet aggregation, and synaptic transmission [91, 95]. Direct desensitization of sGC has not yet been observed; however, signaling through sGC is inhibited downstream via PDE5 and cGMP-dependent protein kinase (PKG) [95].

The membrane-bound (also referred to as particulate) GC family is composed of seven members that also exist as dimers. The atrial natriuretic peptide receptor (GC-A) was the first to be cloned and is activated by atrial or brain natriuretic peptides (ANP or BNP) leading to a net decrease in blood pressure. GC-B is very similar to GC-A but is only activated by c-type natriuretic peptide (CNP) and is mainly associated with bone growth. GC-C is activated by the three related endogenous peptides guanylin, uroguanylin, and lymphoguanylin. GC-A, GC-B, and GC-C are the only GCs where the cognate activator molecules bind to the ECD even though this domain is present in all membrane-bound GCs. Glycosylation and a deeply buried chloride ion are required for proper folding of the ECD to achieve maximal ligand efficacy (reviewed in [91]). In addition, the KHD of these three GCs is a negative regulatory domain that does not possess kinase activity yet requires the binding of ATP to achieve activation of the enzyme [96, 97]. GC-E (or retGC-1) and GC-F (or retGC-2) are retinal GCs that restore intracellular calcium in photoreceptor cells upon light activation [98]. Activation of these GCs differs from GC-A and GC-B in that the activation domain is located intracellularly and is mediated by separate proteins called GC-activating proteins (GCAPs). Ca^{2+} -bound GCAPs bind to the coiled-coil region of the GC-E/GC-F dimer to activate cGMP synthesis (see Fig. 3.4) [99]. The remaining two members of the family GC-D and GC-G are orphan

Figure 3.4 Domain structure of mammalian guanylyl cyclases (GCs). The membrane-bound GC architecture is as follows: extracellular domain (ECD), transmembrane helix (TM), kinase-homology domain (KHD), coiled-coil region (CC), and GC domain. For clarity, the GC-activating protein (GCAP) is shown with only one of its three calcium binding sites. The sites of the postulated conformational changes during GC receptor activation for both the natriuretic peptide receptor and soluble GC are numbered. For GC-A/GC-B, these conformational changes include hormone binding (1), juxtapositioning of the ECD C-termini (2), phosphorylation (3), ATP binding (4), coiled-coil adjustments (5), and conformational changes in the GC domain (6). The precise order of these conformational changes is not known. Furthermore, the activation mechanism likely involves multiple conformational changes at some of these sites to account for outside-in and inside-out signaling as part of the receptor's ability to alter its hormone affinity state upon activation. The heterodimeric soluble guanylyl cyclase (sGC) contains a heme moiety within the N-terminal domain of the β_1 subunit. This latter domain contains the two known steps in the activation process of sGC: NO binding (1) and breakage of the Fe^{2+} -His105 bond (2). Pharmacology and Therapeutics, 104, by P. S. Padayatti, P. Pattanaik, X. Ma, and F. van den Akker. "Structural insights into the regulation and the activation mechanism of mammalian guanylyl cyclases," pp. 83–99 (2004). Adapted with permission from Elsevier.

receptors of unknown function. GC-D is expressed in rat olfactory sensory neurons [100] while GC-G has been localized to lung, intestine, and skeletal muscle [101].

Regulation of GCs by phosphorylation can either be stimulatory or mediate desensitization. Six phosphorylation sites have been identified in GC-A and five sites have been identified in GC-B localized to the KHD in both enzymes. Phosphorylation of these sites results in GC activation, and dephosphorylation at these sites desensitizes the GCs to further stimulation by agonist (reviewed in [91]). GC-C differs from GC-A and GC-B in that phosphorylation of S1029 by PKC activates this receptor [102], and GC-C desensitization is mediated by binding of SH3 domain-containing proteins [103].

3.3.4 Cellular Targets of cGMP

The cellular consequences of synthesizing the second messenger cGMP are mediated by binding of cGMP to three types of cellular substrates: PKG, CNG channels, and PDEs, reminiscent of cAMP signal transduction described above. PDEs can be regulated by either cAMP or cGMP or both or by the cognate receptors activated by the cyclic second messengers. PDE activity can be either enhanced or inhibited by cyclic nucleotide binding, creating positive- or negative-feedback loops for cAMP- and/or cGMP-mediated signaling, resulting in a point of convergence for the two signaling pathways.

PKG is a serine/threonine-directed kinase that exhibits three isoforms grouped into two types that form functional homodimers [104]. Type I PKG exhibits two splice variants I α and I β that differ only in the first 100 amino acids of the protein, are widely distributed, and are usually isolated from soluble tissue extracts [104, 105]. Type II PKG is a monomer of 86 kDa that arises from a separate gene product with an N-terminal domain that differs significantly from the type I PKGs [106]. PKG proteins contain several domains that mediate various functions of the protein. The C-terminal region contains the catalytic domain composed of the ATP and substrate binding sites and exhibits the greatest sequence similarity among the PKG isoforms. Two allosteric cGMP binding sites are located immediately N-terminal to the catalytic domain. Binding of cGMP to these domains initiates conformational changes in the protein that result in activation of enzymatic activity [107]. Upstream from the cGMP binding sites is an autophosphorylation/autoinhibitory domain that contains a pseudosubstrate sequence that binds to and inhibits the catalytic domain. Phosphorylation of sites in and around this region and/or cGMP binding activates PKG I [108, 109], where cGMP binding alone is sufficient for PKG II activation [106]. The N-terminal domain of mammalian PKGs contains six to nine heptad repeats that mediate an extended leucine zipper motif that is required for dimerization of the PKG monomers, resulting in increased affinity for cGMP binding and activation as well as interaction with other proteins [104]. PKG activation and cGMP activation are involved in a variety of cellular activities, including smooth muscle vasorelaxation, regulation of arterial blood pressure, modulation of calcium release by inositol 1,4,5-trisphosphate receptors [110] and NMDA receptor channels [111], and regulation of apoptosis and survival in neural cells [112].

CNG channels represent another cellular target for cGMP binding and regulation. The best characterized examples of CNG channel regulation by cGMP are in the visual and olfactory sensory systems. The photoreceptor cGMP-gated channel consists of 690 amino acids with six transmembrane domains located in the N-terminus and the cGMP binding domain located in the hydrophilic C-terminus, reviewed in [113]. The channel displays a low affinity for cGMP that maintains the channel in an open state due to the unusually high concentration of cGMP in photoreceptor cells (10 μ M). Hydrolysis of cGMP by the transducin-cGMP PDE system closes the channel allowing for the removal of intracellular Ca^{2+} by the $\text{Na}^+ - \text{Ca}^{2+}$ exchanger, gating the system on rapid changes in cGMP concentration. The CNG channel in olfactory epithelium can be gated by either cGMP or cAMP and requires higher concentrations of cGMP for activation than PKG requires [114].

Cyclic nucleotide second messengers are synthesized in response to a variety of cellular stimulants, including hormones, neurotransmitters, and peptides, that bind to cognate receptors that ultimately lead to activation of adenylyl and guanylyl cyclase.

The plethora of mechanisms utilized to synthesize and propagate specific cAMP and cGMP signaling is complex and diverse as discussed above, leading one to wonder how specificity is achieved with such remarkably diverse molecules. Specificity in signaling can be achieved by organizing the key players into supramolecular complexes that are contained in both space and time to direct simultaneous and interconnected signaling pathways into a distinct cellular response. Such a three-dimensional organization of signaling pathways has been the focus of considerable research interest (reviewed in [115]), and is achieved on many levels. First, signal transduction components display a particular pattern of expression within various tissues. Second, coexpression of anchoring proteins such as AKAPs can further discriminate the location of signaling molecules to specific subcellular sites and act as adapter molecules to provide a framework to both orient kinases and phosphatases towards selected substrates and corral signaling gradients. No doubt further experimentation will reveal more participants in the orchestration of cellular signaling.

3.4 PHOSPHOLIPASE C-, PROTEIN KINASE C-, AND Ca^{2+} -REGULATED SIGNALING PATHWAYS

The cellular responses elicited by the interaction of many extracellular signaling molecules with their cell surface receptors are triggered by the rapid hydrolysis of a minor membrane phospholipid, PIP_2 (Fig. 3.5). This reaction is catalyzed by phosphoinositide-specific PLC isozymes and results in the generation of two intracellular messengers, DAG and inositol 1,4,5-trisphosphate (IP_3). These messengers then promote the activation of PKC and the release of Ca^{2+} from intracellular stores, respectively. The PLC isozymes responsible for the generation of IP_3 and DAG have been classified on the basis of amino acid sequence into five major types (Fig. 3.6). These groups also differ in the mechanism by which the isozymes are activated in response to ligand interaction with various receptors. For example, $\text{PLC}\beta$ has been shown to be activated by GPCRs through $\text{G}\alpha_q$ or $\text{G}\beta\gamma$ and $\text{PLC}\gamma$ isozymes are regulated by receptor and nonreceptor tyrosine kinases.

3.4.1 IP_3 and Phosphoinositides as Signaling Molecules

IP_3 , generated from PIP_2 following agonist-dependent activation of PLC, is highly mobile and diffuses into the cytoplasm. There it releases Ca^{2+} from the endoplasmic reticulum (ER) by binding to an IP_3 receptor (IP_3R), which is an IP_3 -gated Ca^{2+} release channel in the ER membrane. IP_3 is further converted by the action of several distinct kinases and phosphatases to a variety of inositol phosphates, some of which are also implicated in intracellular signaling. Finally, it is sequentially dephosphorylated to free inositol, which can be reutilized by phosphatidylinositol (PI) synthase to form PI. PI is sequentially phosphorylated to form phosphatidylinositol phosphate (PIP) and PIP_2 (Fig. 3.7).

PIP_2 not only serves as the source of DAG and IP_3 but is also a substrate of another receptor-activated enzyme, PI 3-kinase (PI3K). Phosphorylation of PIP_2 by PI3K yields phosphatidylinositol 3,4,5-trisphosphate (PIP_3), which functions as a distinct second messenger. Signaling proteins (mostly kinases) with pleckstrin homology (PH) domains accumulate at sites of PI3K activation by directly binding

Figure 3.5 Hydrolysis of PIP₂ by phospholipase C. The structure shows phosphatidylinositol 4,5-bisphosphate PIP₂, which contains a phosphorylated inositol head group connected to a DAG via a phosphodiester linkage. The fatty acid moiety is typically stearyl-arachidonyl. Phospholipase C hydrolyzes PIP₂ into inositol 1,4,5-trisphosphate [Ins(1,4,5)P₃] and DAG.

to PIP₃ [116]. The formation of PIP₃ thus provides an anchor for assembling signaling proteins at specific locations in the membrane in response to cell stimulation. These signaling proteins coordinate complex events leading to changes in cell metabolism, growth, movement, and survival.

In addition, PIP₂ is a signaling molecule in its own right [117]. High-affinity binding of PIP₂ to a number of proteins causes them to relocate to the plasma membrane, and this is typically mediated by the PH domain of phospholipases (e.g., PLC δ -1) and exchange factors of GTPase (e.g., Sos, Vov). Finally, PIP₂ regulates the organization of the actin cytoskeleton, the activities and localization of proteins involved in vesicle trafficking, the activity of many ion channels and transporters, and the recruitment of cytosolic proteins to specific membranes [118].

Lithium has been used for the treatment of bipolar disorder since the 1960s. However, the mechanism of lithium action is still unclear. Lithium inhibits inositol monophosphatase, which is an enzyme of the last common step of dephosphorylation of inositol phosphates (Fig. 3.7). All inositol monophosphate are metabolized by

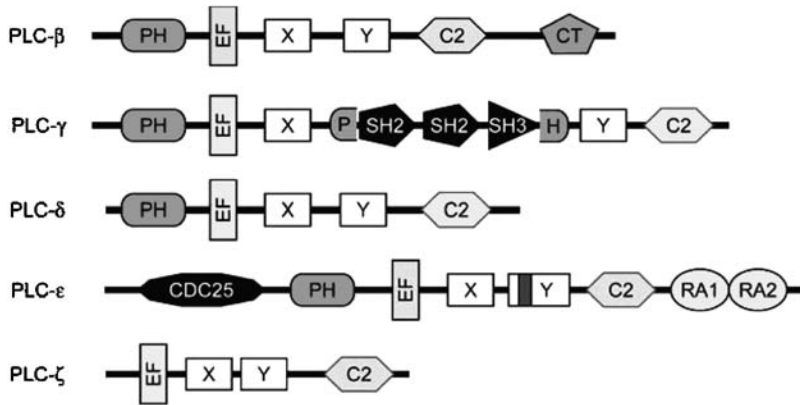

Figure 3.6 Domain structure of mammalian PLC family members. Hallmarks of PLC family members are an N-terminal PH domain, which binds PIP_2 and $\text{G}\beta\gamma$ subunits, and EF, X, Y, and C2 motifs forming the catalytic core for phosphoinositide hydrolysis. $\text{PLC}\beta$ can be activated by $\text{G}\alpha_q$ through unique C-terminal (CT) domain, which also acts as a $\text{G}\alpha_q$ GAP. Unique to $\text{PLC}\gamma$ are two Src homology 2 (SH2) domains and a Src homology 3 (SH3) domain that bisect the pleckstrin homology (PH) domain. The SH2 domains confer sensitivity to stimulation by growth factors like platelet-derived growth factor (PDGF) or epidermal growth factor (EGF) receptors. $\text{PLC}\epsilon$ differs from the other types of isoforms in that it possesses an NH_2 -terminal Ras guanine nucleotide exchange factor (RasGEF, cdc25)-like domain and at least one and perhaps two COOH terminal Ras binding (RA) domains. $\text{PLC}\delta$ isoform may be regulated by Ca^{2+} ; however, the mechanisms by which $\text{PLC}\delta$ enzymes couple to and are regulated by the membrane receptor is less clear. $\text{PLC}\zeta$, the most recently identified PLC isoform, is reportedly responsible for sperm-mediated Ca^{2+} oscillations that occur during fertilization. (From [2] with permission from Birkhäuser Publishing, Basel, Switzerland.)

inositol monophosphatase. The de novo synthesis of *myo*-inositol also occurs by isomerization of glucose 6-phosphate to form IP_1 . Thus in the presence of lithium, these monophosphates cannot be dephosphorylated to yield free inositol, which is required to regenerate PIP_2 . Because *myo*-inositol is essential for the formation of PIs, it is hypothesized that lithium's therapeutic action is mediated by reducing levels of inositol in the brains of patients with bipolar disorder [119]. While the inositol depletion hypothesis still offers an attractive mechanism of lithium efficacy, its validity remains to be demonstrated [120].

3.4.2 Ca^{2+} as a Signaling Molecule

Calcium (Ca^{2+}) is a ubiquitous intracellular signal responsible for controlling numerous cellular processes. Cells at rest have a Ca^{2+} concentration of 100 nM but are activated when this level rises to roughly 1 μM . Cells generate their Ca^{2+} signals by using both internal and external sources of Ca^{2+} . There are several pathways for the entry of external Ca^{2+} into the cell: (1) Voltage-operated Ca^{2+} channels, which are plasma membrane ion channels, are activated by membrane depolarization. (2) Receptor-operated Ca^{2+} channels open in response to receptor activation by extracellular ligand, such as nicotinic acetylcholine receptor and NMDA receptor. (3) Store-operated Ca^{2+} channels open in response to depletion

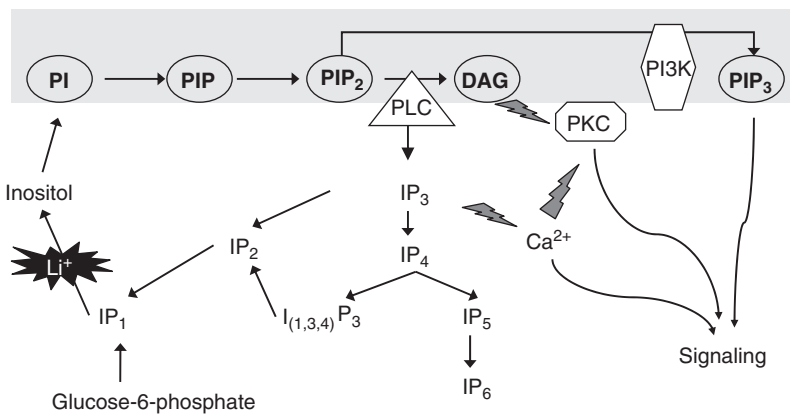

Figure 3.7 Biosynthesis and metabolism of phosphoinositide signals. Inositol is transferred to DAG and phosphorylated to form PIP₂ in the membrane. Cell stimulation activates PLC to release DAG and the soluble second messenger Ins(1,4,5)P₃. Ins(1,4,5)P₃ diffuses through the cytosol and releases Ca²⁺ from the ER and DAG remains in the membrane and activates PKC. Activation of PI3K by extracellular stimuli also phosphorylates PIP₂ into PIP₃, which regulates many signaling enzymes. Ins(1,4,5)P₃ is further phosphorylated to form the higher order InsP (InsP₄, InsP₅, and InsP₆) or dephosphorylated and recycled into inositol. All inositol monophosphates (InsP₁) are metabolized by inositol monophosphatase, an enzyme that is inhibited by lithium (Li⁺). The de novo synthesis of *myo*-inositol also occurs by isomerization of glucose 6-phosphate to form InsP₁. Thus in the presence of lithium, these monophosphates cannot be dephosphorylated to yield free inositol, which is required to regenerate PIP₂. Lithium also inhibits inositol polyphosphate-1-phosphatase, which hydrolyzes Ins(1,3,4)P₃ to Ins(3,4)P₂ and Ins(1,4)P₂ to Ins4P.

of internal Ca^{2+} stores. The mechanism by which those channels “sense” the filling status of the intracellular pool is unknown. The internal stores are held within the membrane systems of the ER or the equivalent organelle, the sarcoplasmic reticulum (SR) of muscle cells. Release from these internal stores is controlled by various channels, of which the IP_3R and ryanodine receptor (R YR) families have been studied most extensively. Intracellular messenger IP_3 , produced by the hydrolysis of PIP_2 by a family of PLC, binds IP_3R and releases Ca^{2+} from the ER. Most of the Ca^{2+} that enters the cytoplasm is rapidly bound to various cytosolic buffers such as parvalbumin, calbindin, and calretinin. Cytosolic buffers are involved in the shaping and duration of Ca^{2+} signals and also limit the spatial spreading of local Ca^{2+} signals [121]. This is particularly important in neurons that contain high concentrations of buffers, such as parvalbumin and calbindin, which ensure that Ca^{2+} signals are largely confined to synapses. Once Ca^{2+} has carried out its signaling functions, it is rapidly removed from the cytoplasm by various pumps and exchangers. The plasma membrane Ca^{2+} -ATPase pumps and Na^{+} - Ca^{2+} exchangers extrude Ca^{2+} to the outside whereas the sarco-ER ATPase pumps return Ca^{2+} to the internal stores.

3.4.3 DAG Activates Protein Kinase C

At the same time that the IP₃ produced by hydrolysis of PIP₂ is increasing the concentration of Ca²⁺ in the cytosol, the other cleavage product of PIP₂—DAG—is

exerting different effects. The hydrophobic DAG that remains within the plane of the plasma membrane functions as a second messenger by activating PKC. In the absence of hormone stimulation, PKC is present as a soluble cytosolic protein that is catalytically inactive [122]. A rise in the cytosolic Ca^{2+} level causes PKC to bind to the plasma membrane, where it can be activated by the membrane-associated DAG. In addition to DAG and Ca^{2+} , the enzyme requires phosphatidylserine (PS). Thus activation of PKC depends on both Ca^{2+} ions and DAG, suggesting an interaction between the two branches of the inositol-lipid signaling pathway. Prolonged activation of PKC can be accomplished with phorbol esters, tumor-promoting compounds that activate PKC by mimicking DAG. PKC is also regulated by autophosphorylation and transphosphorylation on tyrosine and/or serine/threonine residues by upstream kinases. Phosphorylation of PKC by these kinases induces maturation of the PKC enzyme as well as activating its enzymatic activity.

The PKC families are divided into three groups according to their regulatory properties [123, 124] (Fig. 3.8). Conventional PKC isozymes (α , γ , and the alternatively spliced βI and βII) are stimulated by DAG, PS, and Ca^{2+} ; novel PKC isozymes (δ , ϵ , η , θ) are stimulated by DAG and PS; atypical PKC isozymes (ς , ι/λ) are stimulated by PS and do not respond directly to either DAG or Ca^{2+} . Since the multiple PKC isoforms are discrete functional entities with distinct cellular and subcellular localizations, it is likely that they possess unique patterns of sensitivity in input signals. In the nervous system, activation of PKC has been related to enhancement of neurotransmitter release, regulation of ion channels, control of growth and differentiation, and modification of neuronal plasticity. The mechanism of action of PKC and the physiological substrates of PKC in controlling these neural functions are still poorly characterized. Identification of specific substrates for each PKC species at different cellular and subcellular locations is essential to understanding the physiological functions of these enzymes.

3.4.4 Action of Ca^{2+} and Its Mediator Calmodulin

Ca^{2+} is an almost universal intracellular messenger, controlling a diverse range of cellular processes, such as gene transcription, muscle contraction, neurotransmitter or hormone release, and cell proliferation. How do Ca^{2+} signals produce changes in cell function? The information encoded in transient Ca^{2+} signals is deciphered by various intracellular Ca^{2+} binding proteins that convert the signals into a wide variety of biochemical changes. Ca^{2+} binding proteins can be divided into Ca^{2+} buffers (described above) and Ca^{2+} sensors on the basis of their main functions. The latter respond to an increase in Ca^{2+} by activating diverse processes. Some Ca^{2+} sensors, such as PKC, bind to Ca^{2+} and are directly regulated in a Ca^{2+} -dependent manner. Other Ca^{2+} -sensor proteins, however, are intermediaries that couple the Ca^{2+} signals to biochemical and cellular changes. The most prominent examples of sensors include troponin C (a protein dedicated to regulating cardiac and skeletal muscle contraction) and the multifunctional Ca^{2+} transducer calmodulin (CaM).

CaM is used more generally to regulate many processes such as the contraction of smooth muscle cells, crosstalk between signaling pathways, gene transcription, ion channel modification, and metabolism. CaM is a ubiquitous, multifunctional Ca^{2+} binding protein with a molecular weight of approximately 17 kDa. The binding of Ca^{2+} enhances CaM's affinity for most of its target proteins. These changes in

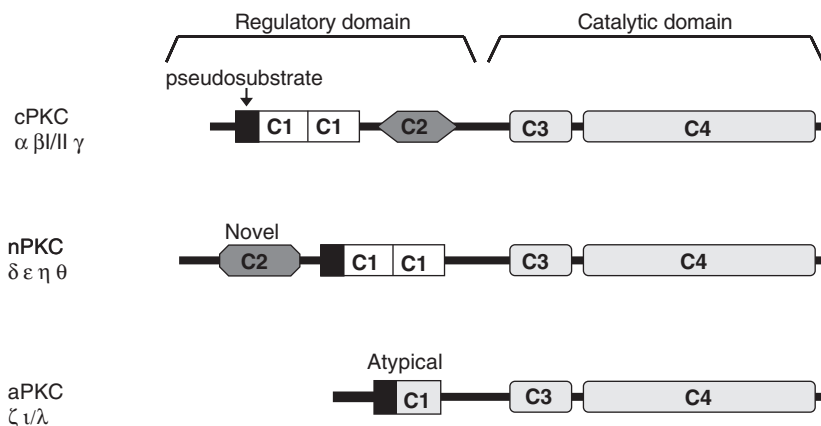

Figure 3.8 Domain structure of mammalian PKC family members. All PKCs contain a C-terminal catalytic domain and an N-terminal regulatory domain. The catalytic domain is highly conserved in PKC family members and is comprised of two regions: the ATP binding lobe (C3) and the substrate binding lobe (C4). It is maintained in an inactive state by an autoinhibitory sequence in the regulatory moiety, the pseudosubstrate (black box), that sterically blocks the active site. The regulatory domains are more diverse and define three classes of PKC. Conventional PKC (cPKC) isoforms have a Ca^{2+} binding C2 domain and tandem DAG binding C1 domains, conferring a dependence on both Ca^{2+} and DAG for high-affinity membrane binding and maximal kinase activity. Novel (nPKC) isoforms have a novel variant of the C2 domain that does not bind Ca^{2+} and two conventional C1 domains; these isoforms are DAG dependent but Ca^{2+} independent. Atypical (aPKC) isoforms have no C2 domain and a single C1 domain that does not bind DAG, and so are Ca^{2+} and DAG independent; atypical PKC isoforms depend only on phosphatidylserine and phosphorylation for activation. The role of the novel C2 domain in nPKCs and that of the atypical C1 domain in aPKCs is not clear, but each may regulate the subcellular distribution of these isoforms through protein–protein interactions. (Adapted from [125a].)

affinity occur because Ca^{2+} binding induces a conformational change in CaM. Studies on crystal structure show that CaM is a symmetrical dumbbell-shaped molecule with two Ca^{2+} binding domains on each end connected by an α -helical structure [125]. The K_d for the binding of the four Ca^{2+} molecules to CaM are in the micromolar range, with two higher and two lower affinity sites. Ca^{2+} -dependent binding of CaM to many proteins or enzymes would occur primarily in response to cell activation as opposed to resting Ca^{2+} levels, although CaM can bind several proteins in the absence of Ca^{2+} . Thus, hormones and neurotransmitters that elevate intracellular Ca^{2+} can activate CaM-dependent processes that will contribute to the physiological responses. Moreover, Ca^{2+} binding to the low-affinity sites of CaM is greatly enhanced in the presence of a CaM binding enzyme [126]. The affinity for Ca^{2+} of each CaM binding enzyme complex is unique to that complex. Therefore, different enzymes can have different Ca^{2+} sensitivities, despite being activated through the same CaM.

The Ca^{2+} –CaM complex stimulates a wide array of enzymes, pumps, and other target proteins. Interestingly, many of the most highly characterized effectors are directly (protein kinase/phosphatase) or indirectly (adenylyl cyclase/phosphodiesterase) involved in protein phosphorylation [127]. For example, calmodulin kinase II

(CaMKII) is a major target of the Ca^{2+} /CaM second-messenger system. These enzymes regulate fuel metabolism, ionic permeability, neurotransmitter synthesis, neurotransmitter release, and learning and memory. Once bound to Ca^{2+} /CaM, the multimeric CaMKII is released from its autoinhibitory status and maximally activated, which then leads to an intraholoenzyme autophosphorylation reaction. Autophosphorylation of CaMKII makes it independent of Ca^{2+} and renders it constitutively active and, in essence, it is the memory of a previous calcium pulse. Calcineurin (also known as protein phosphatase 2B) is another major target protein that is activated by Ca^{2+} /CaM. Calcineurin is a serine–threonine phosphatase that consists of a heterodimeric protein complex composed of a catalytic subunit (CNA α or CNA β) and a regulatory subunit (CNB1). Upon activation, calcineurin directly binds to and dephosphorylates the nuclear factor of activated T cells (NF-AT) transcription factors within the cytoplasm allowing them to translocate to the nucleus and participate in the regulation of gene expression. Ca^{2+} /CaM can also regulate intracellular cAMP levels through two opposite reactions: activation of adenylyl cyclase 1 and 8 or stimulation of some of the cAMP phosphodiesterases; these enzymes degrade cAMP and terminate its effects. Those reactions thus link Ca^{2+} and cAMP, one of many examples in which these two second messengers interact to fine tune certain aspects of cell regulation. The plasma membrane Ca^{2+} –ATPase pump, various ion channels, the ryanodine receptor, and isoforms of the IP₃ receptor are other important targets of Ca^{2+} /CaM.

3.5 PROTEIN PHOSPHORYLATION

Protein phosphorylation is a prominent feature of many signaling pathways. The reversible covalent attachment of a phosphate group to cellular proteins can have profound effects on the protein's activities and properties. The ability of a cell to phosphorylate and dephosphorylate a substrate is intricately regulated by the interplay of protein kinases and protein phosphatases. Protein kinases and phosphatases are broadly divided into groups based on their abilities to phosphorylate specific amino acids (i.e., serine/threonine or tyrosine), although this classification is not exclusive and in fact several kinases and phosphatases exhibit dual specificity. This section will focus on several families of kinases and phosphatases that are critical for the control of many processes that include cellular proliferation, differentiation, apoptosis, and synaptic plasticity.

3.5.1 Protein Tyrosine Kinases

Protein tyrosine kinases (PTKs) catalyze the transfer of phosphate to tyrosine residues in polypeptide. PTKs are divided into two main classes: receptor and non receptor tyrosine kinases. Receptor tyrosine kinases (RTKs) are monomeric transmembrane proteins with an intracellular catalytic kinase domain and an extracellular ligand binding domain. Examples of RTKs include the epidermal growth factor receptor (EGFR) family, neurotrophin receptor family, and Eph receptor family.

RTKs generally reside within a cell in an unphosphorylated monomeric conformation. Activation of RTKs requires ligand binding to the extracellular domain and dimerization of two ligand-bound receptors (Fig. 3.9). However, RTK

activation is not limited to homodimerization and crosstalk between heterodimers of related RTK families has been reported [128]. The interaction of adjacent intracellular RTK domains disrupts the autoinhibitory constraints and permits the transphosphorylation of tyrosine residues within their cytoplasmic regions. Once activated, the phosphotyrosine residues of RTKs provide docking sites for the recruitment of signaling proteins to the cell membrane, leading to the propagation of multiple signaling cascades [129]. Many signaling proteins recruited to RTKs contain SH2 (src-homology 2) and/or PTB (phosphotyrosine binding) domains [130]. These domains recognize and bind to phosphotyrosine residues and their surrounding structures. A diverse array of SH2- containing proteins, ranging from scaffolding

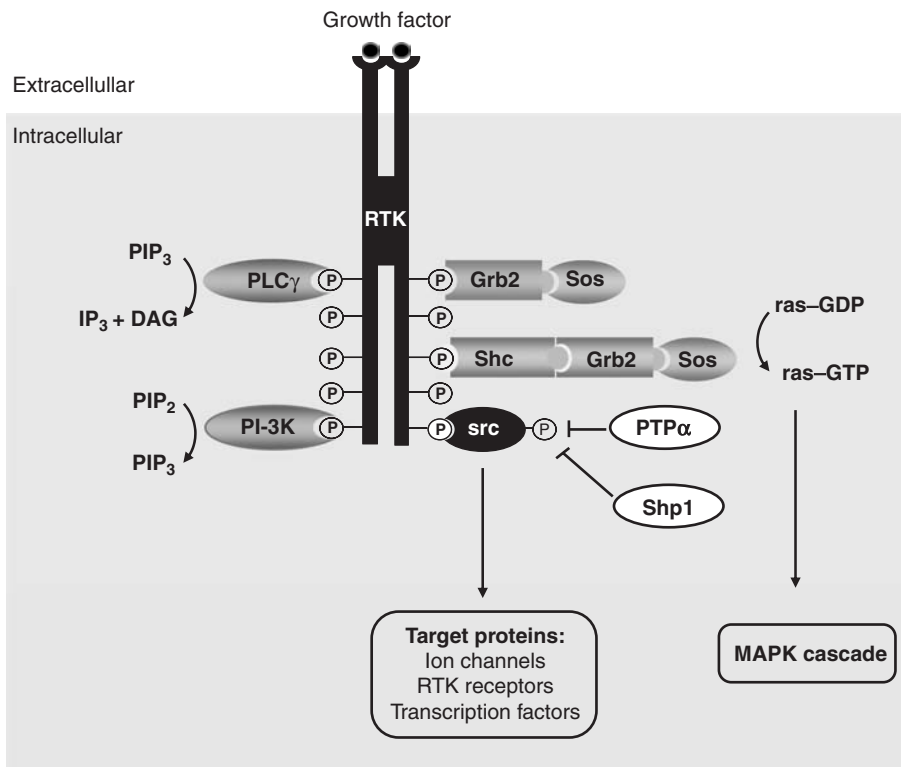

Figure 3.9 Receptor and nonreceptor tyrosine kinase signaling pathways. Dimerization of ligand-bound receptor RTKs activates their kinase domain resulting in transphosphorylation. Phosphotyrosine residues of RTKs recruit SH2-containing proteins such as the adapter proteins Grb2 and Shc. Association of Sos with Grb2 positions Sos in proximity to Ras. Sos activates Ras by exchanging GDP for GTP. Ras-GTP activates the MAPK cascade. The SH2-containing enzymes PLC γ and p85 (the regulatory domain of PI-3 kinase) also associate with phosphotyrosine residues of RTKs and are activated either by tyrosine phosphorylation or release of autoinhibitory constraints, respectively. PLC γ catalyzes the hydrolysis of PIP_2 and the generation of IP_3 and DAG. PI-3 kinase catalyzes the phosphorylation of PIP and PIP_2 to generate PIP_2 and PIP_3 , respectively. The SH2 domains of the nonreceptor tyrosine kinase Src also associate with activated RTKs. Src is activated by both dephosphorylation and phosphorylation events mediated in part by the phosphatases $PTP\alpha$ /Shp1 and kinase activity of the EGF receptor.

molecules to enzymes, can associate with activated RTKs and elicit multiple signaling pathways. For example, PLC γ and the regulatory domain of PI-3 kinase (p85) bind to phosphotyrosine residues of PDGF receptors and are activated by tyrosine phosphorylation or release of an autoinhibitory constraint, respectively. Similarly, the adapter proteins Grb2 and Shc also associate with the phosphotyrosine residues of RTKs and activate several signaling pathways such as the Ras-MAP kinase cascade [129].

The nonreceptor tyrosine kinases (nRTKs) lack transmembrane domains and are localized in the cytosol, inner surface of the plasma membrane, and nucleus. They include members of the Abl, Src, JAK, FAK, and Syk families. The Src family is the largest family of nonreceptor tyrosine kinases and is comprised of nine members, including Src itself [131].

Regulation of the Src family kinases is intricate and dependent on the interplay between kinases, phosphatases, and protein–protein interactions via their multiple SH domains [132]. SH1 is the catalytic domain of Src and is maintained inactive by impeding substrate access. Substrate accessibility is blocked by several intramolecular mechanisms that include positioning of a key regulatory tyrosine within the catalytic domain and binding of a constitutively phosphorylated tyrosine residue in the carboxy terminus to an upstream SH2 domain. Substrate access to the catalytic site of Src requires both phosphorylation and dephosphorylation events, specifically dephosphorylation of the phosphotyrosine residue associated with SH2 binding and phosphorylation of the regulatory tyrosine within the kinase domain [133, 134].

The subcellular localization of Src regulates its catalytic activity. The trafficking of Src to the plasma membrane and association with specific membrane proteins is critical for controlled kinase activity. Src tethers to the plasma membrane by covalently attached lipid chains that position the kinase in proximity to transmembrane receptors such as the EGFR [135]. The SH2 domain of Src associates with the phosphotyrosine residues of the EGFR (Fig. 3.9). The EGFR activates Src by phosphorylating key tyrosine residues. Once activated, Src phosphorylates many target proteins that include the EGFR, ion channels, synaptic vesicle proteins, and transcription factors [136–139].

3.5.2 Mitogen-Activated Protein Kinases

The MAPKs are a family of serine/threonine kinases that catalyze the transfer of phosphate to serine and threonine residues within a specific protein. MAPKs propagate a cascade of intracellular phosphorylation events in response to a variety of extracellular signaling stimuli. To date, four MAPK cascades have been identified in mammalian cells. They are the ERK1/ERK2 (extracellular signal-regulated kinase), ERK5 (or big MAPK), JNK/stress-activated protein kinase (SAPK), and p38 kinase cascades [140] (Fig. 3.10). Each MAPK cascade displays a high degree of specificity and in general is functionally separate from the others.

The ERK1/ERK2 cascade is activated in response to cues that promote proliferation and differentiation, such as growth factors and the activation of their receptors [141]. Crosstalk between growth factor receptors, such as the EGFR, and the ERK1/2 kinase cascade is relayed by a number of adapter/scaffolding molecules that include the previously mentioned Grb2. Association of Grb2 with the phosphorylated EGFR promotes the recruitment of Sos (a guanine nucleotide binding protein) to the plasma

membrane, positioning it in close proximity to membrane-bound Ras [142, 143]. Sos activates Ras-GDP by exchanging GDP for GTP. Ras-GTP activates Raf, a MAP kinase kinase kinase (MKKK). Raf is a serine/threonine kinase that phosphorylates MEKK, a MAP kinase kinase (MKK). Raf phosphorylates MEK on two serine residues within the consensus sequence S-X-X-X-S/T resulting in MEK activation. MEK is a dual-specificity enzyme that activates the MAP kinase, ERK1/2, by phosphorylating both threonine and tyrosine residues in the consensus sequence TEY (reviewed in [140]). Once activated, ERK1/2 translocates to the nucleus and phosphorylates several target proteins, including the transcription factor Elk-1 (Fig. 3.10) [144]. ERK1/2 activity is not restricted to nuclear targets and includes cytoskeletal proteins, cytoplasmic kinases, and growth factor receptors [145–148].

The JNK/SAPK and p38 kinase cascades respond mainly to stress signals, such as ultraviolet irradiation and proinflammatory cytokines, whereas the ERK5 pathway can transmit both mitogenic and stress signals. The ERK5, JNK/SAPK, and p38 kinase cascades follow the same principles of the ERK1/ERK2 pathway involving a series of consecutive phosphorylation steps that ultimately result in activation of a specific MAPK (Fig. 3.10). Once phosphorylated and activated, ERK5, JNK/SAPK, and p38 can translocate to the nucleus and regulate the activity of transcription factors (Fig. 3.10). Similar to ERK1/2, JNK/SAPK and p38 can phosphorylate several cytosolic proteins [140].

Although each MAPK cascade shows a high degree of specificity and functional separation, crosstalk between these pathways has been reported. For example, MEK1/MEK2 and MKK3 are the only known activators of ERK1/2 and p38, respectively [149, 150]; however, MKK4 is capable of activating both the JNK/SAPK and p38 pathways [150, 151].

3.5.3 G-Protein-Coupled Receptor Kinases

G-protein-coupled receptor kinases (GRKs) phosphorylate serine/threonine residues of agonist-occupied GPCRs and play a key role in GPCR desensitization (homologous desensitization). To date, seven mammalian genes encoding GRKs (GRK 1–7) have been identified. The majority of GRKs are ubiquitously expressed with the exception of GRK4 and GRK1/7. GRK4 is expressed in the testis, brain, myometrium, and kidney. In contrast, GRK1/7 are exclusively expressed in the retina [152].

Cellular compartmentalization is an important feature of regulated GRK signaling. This is achieved through several distinct mechanisms that are GRK-subtype specific. For example, posttranslational lipid attachment and modification to the carboxyl terminus of GRK1 and GRK4/6 is required for membrane localization and positioning of the GRK in close proximity to the receptor substrate [153–155]. Alternatively, some GRKs (i.e., GRK2 and GRK3) are ferried to the plasma membrane by a cooperative attachment to $\beta\gamma$ subunits that are released from the G-protein trimer upon activation of a GPCR [156, 157].

The molecular events underlying GRK-mediated GPCR phosphorylation, desensitization, and internalization occur in a sequential manner (Fig. 3.11). GRKs associate exclusively with the active (agonist-bound) GPCR conformation. GRK association with its activated receptor is an important initial step for GRK-mediated receptor phosphorylation and can be impaired or enhanced by the association of Ca^{2+} binding proteins, autophosphorylation or PKC phosphorylation of specific GRK subtypes.

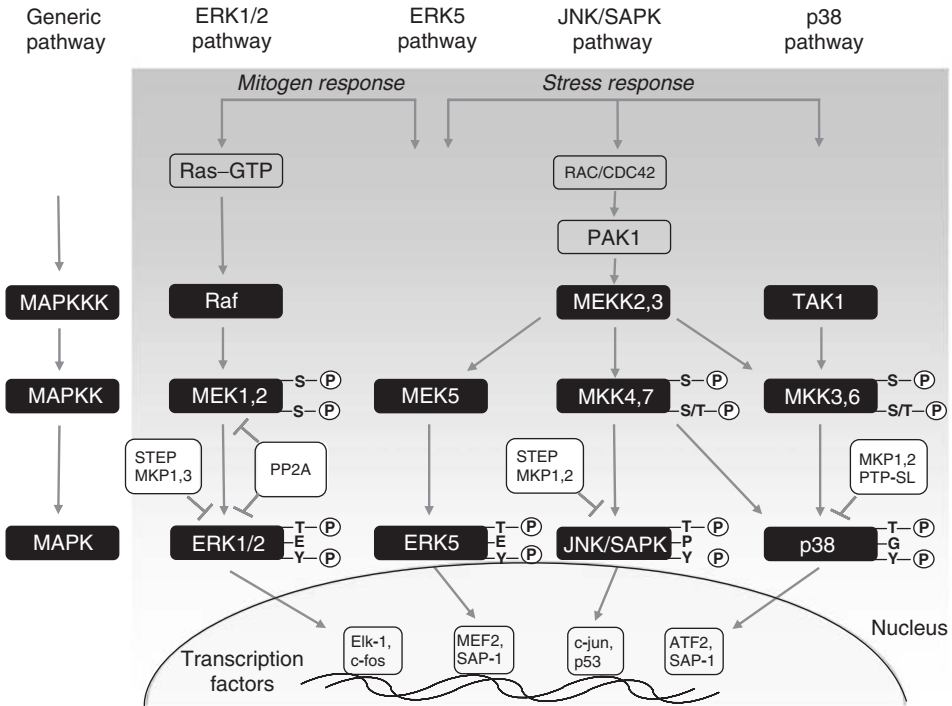

Figure 3.10 Schematic representation of MAPK cascades. A variety of signals trigger mitogenic or stress responses and these signals are transmitted to the interior of the cells where they activate appropriate cascades. Each of the four MAPK cascades (ERK1/2, ERK2, JNK/SAPK, and p38) consists of a three-enzyme module that includes MAPKKK, MAPKK, and MAPK (black boxes). These cascades are inhibited by phosphatases (white boxes).

The association of the Ca^{2+} binding proteins calmodulin and recoverin generally impairs receptor–GRK association. For example, calmodulin specifically inhibits GRK2/5–receptor association whereas recoverin specifically inhibits GRK1 [158, 159]. GRK1 and GRK5 are autophosphorylated, a modification that also impairs receptor interactions [160, 161]. In particular, GRK1 autophosphorylation inhibits its association with the phosphorylated receptor substrate—a mechanism believed to facilitate dissociation of the GRK–receptor complex following receptor phosphorylation [162]. GRK2 and GRK5 are also substrates for PKC phosphorylation, although the functional consequences are different for the two subtypes. GRK2 activity is enhanced by PKC phosphorylation whereas GRK5 activity is reduced [163, 164].

Generally, GRKs phosphorylate serine/threonine residues within the intracellular loops and/or the C-terminus of GPCRs. Although a GRK-specific phosphorylation consensus sequence has not been identified, GRK1 and GRK2 preferentially phosphorylate serine/threonine residues flanked by acidic residues on the carboxyl or amino terminal sides, respectively [165]. GRK5 and GRK6, on the other hand, phosphorylate serine residues that are downstream from basic amino acids [166, 167]. The phosphorylated receptor–GRK complex provides a platform for the association of arrestin. Arrestin association to the receptor–GRK complex prevents the exchange

Figure 3.11 Schematic diagram representing GRK-mediated regulation of GPCRs. Following agonist binding, GPCRs activate heterotrimeric G proteins that in turn couple to effectors such as adenylyl cyclase, PLC β , and p115 RhoGEF. GRKs phosphorylate the agonist-bound form of the receptor and uncouple GPCRs from G proteins. The phosphorylated receptor recruits arrestin, further hindering association with G proteins. AP2 and clathrin associate with the receptor/arrestin complex and internalize the phosphorylated receptor into clathrin-coated pits. (Reproduced from [168].)

of GTP for GDP on the G-protein α subunit and desensitizes the receptors response. Subsequent association with the adapter protein AP2 and clathrin facilitates the internalization of desensitized receptors into clathrin-coated pits (reviewed in [168]).

In addition to receptor desensitization and internalization, GRKs and arrestins act as adapter molecules in their own right, shuttling additional signaling proteins to activated receptors, ultimately tethering GPCR signaling to noncanonical pathways [168].

3.5.4 Protein Tyrosine Phosphatases

Protein tyrosine phosphatases (PTPs) hydrolyze phosphotyrosine residues of a polypeptide. The tyrosine-specific phosphatases are subdivided into two groups: the receptor like PTPs (RPTPs) and the intracellular PTPs.

To date, eight RPTP subgroups have been identified based on sequence motifs in their diverse extracellular domains [169]. RPTPs usually possess two intracellular phosphatase domains, a transmembrane domain and a highly variable extracellular domain. The first phosphatase domain (membrane proximal) is responsible for >90% of catalytic activity, while the second phosphatase domain binds multiple downstream partners [170]. Although RPTPs are capable of forming homodimers and heterodimers with other RPTPs, they are catalytically active as monomers and dimerization in some cases inhibits their activity by preventing substrate access [171].

PTP α is an RPTP expressed in the brain and kidney that regulates the activity of several proteins, including the tyrosine kinase Src and the adapter protein Grb2 (Fig. 3.12). The SH2 domain of Grb2 associates with a constitutively phosphorylated tyrosine residue of PTP α . Upon PKC δ phosphorylation of PTP α , Grb2 is exchanged for Src, whose SH2 domain associates with the phosphotyrosine residues of PTP α . Through a phosphotyrosine displacement mechanism, the inhibitory C-terminal phosphotyrosine residue of Src is released and dephosphorylated by PTP α , thus activating Src. Grb2 is subsequently released from PTP α and free to associate with Sos via its SH3 domain [172, 173].

Intracellular tyrosine phosphatases, in contrast to RPTPs, lack transmembrane and extracellular domains and possess only one phosphatase domain. The intracellular tyrosine phosphatases are subdivided into two groups: tyrosine specific that include SHP (src homology protein) 1 and 2 and STEP (striatal enriched phosphatase).

Figure 3.12 Role of phosphatases in dopamine and NMDA signaling pathways. Both glutamatergic and dopaminergic systems interact with DARPP-32. The D₁ dopamine receptor activates PKA by increasing cAMP levels. PKA phosphorylates dopamine- and CAMP-regulated phosphoprotein (DARPP-32) converting it to a potent inhibitor of the phosphatase PP1. Conversely, activation of the D₂ dopamine receptor reduces PKA-dependent phosphorylation of DARPP-32 by decreasing cAMP levels. DARPP-32 activity is also regulated by calcineurin. A major source of calcium fluctuation in the cell is through the opening and closing of NMDA receptors. Calcium activates calcineurin both directly and through interactions with calmodulin. Calcineurin indirectly activates PP1 activity by dephosphorylating and inactivating DARPP-32 and inhibitor 1. A target of PP1 activity is the tyrosine phosphatase STEP. (Reproduced from [189].)

tase) and dual-specificity phosphatases such as dsMKPs (mitogen-activated protein kinase phosphatases) and PTEN (phosphatase and tensin homolog). In general, the dual-specificity phosphatases hydrolyze phosphorylated serine, threonine, and tyrosine residues. However, PTEN is more unusual and can dephosphorylate both phosphotyrosine and the lipid phosphatidylinositol 3,4,5-triphosphate [174].

The dsMKPs are important regulators of the MAPK cascades. They inactivate members of the MAPK pathways by dephosphorylating both tyrosine and threonine residues and display unique yet overlapping substrate specificities (Fig. 3.10). For example, MKP1 dephosphorylates ERK, JNK, and p38 whereas MKP2 is selective for JNK and ERK. Even more selective is MKP3, whose target kinase is only ERK1/2 [175]. Selectivity of MKP activity is accomplished, in part, through protein–protein interactions that are independent from the phosphatase domain. In particular, a kinase interaction motif (KIM) located at the amino terminal of MKP3 directly and specifically interacts with the ERK1/2. Furthermore, MKP3 is activated by ERK1/2 [176, 177].

The regulation of MKPs is complex. Some are constitutively active (MKP3) whereas others are induced in response to specific cues (MKP1 and MKP2). Moreover, the expression of some MKPs is restricted to specific subcellular compartments; MKP3 is exclusively cytosolic versus MKP1 expression in the nucleus. MKP activity is also regulated by phosphorylation. For example, direct phosphorylation of MKP1 by ERK reduces MKP1 ubiquitination and proteasomal degradation [175].

The tyrosine phosphatase STEP also regulates the activity of the MAPK members ERK1/2 and p38 (Fig. 3.10). Similar to MKP3, the KIM domains of STEP bind ERK1/2 and inactivate the kinase's activity by dephosphorylating the regulatory tyrosine residue [178]. The enzymatic activity of STEP in neurons is regulated by phosphorylation and dephosphorylation events that are dictated in part by the dopamine D₁ receptor and glutamate NMDA receptor, respectively [179, 180]. Specifically, PKA-dependent phosphorylation of the regulatory serine within the KIM domain of STEP sterically prevents interactions with ERKs. Conversely, PP1-dependent dephosphorylation activates STEP. The regulation of phosphatases by the dopaminergic and glutaminergic pathways is described in greater detail below.

3.5.5 Serine/Threonine Phosphatases

Protein phosphatases that catalyze the dephosphorylation of serine and threonine residues have been classified into four major subtypes based on biological characteristics, sensitivities to specific inhibitors, and substrate specificities: PP1, PP2A, PP2B (also known as calcineurin), and PP2C. Other serine/threonine phosphatases identified include PP4, PP5, PP6, and PP7. PP1, PP2A, and PP2B are composed of catalytic and regulatory subunits. In contrast, PP2C exists as a monomer that is devoid of regulatory subunits and dependent on Mg^{2+} and Mn^{2+} [181].

Multiple mechanisms tightly regulate the activity, substrate specificity, and intracellular localization of protein phosphatases. In many instances, the catalytic subunits are associated with regulatory/targeting proteins that ultimately dictate the subcellular localization and substrate specificity of a phosphatase. Several phosphatase-interacting proteins have been identified that are important for localizing phosphatases in close proximity to their target proteins. For example, AKAP

functions as a scaffolding molecule that tethers calcineurin to the NMDA receptor [182]. PP1, on the other hand, is localized to neurotransmitter receptors such as the dopamine D₂ receptor by association with the PDZ domain containing the protein spinophilin [183]. In addition to proteins that are involved in the correct localization of phosphatases, several endogenous phosphatase activators/inhibitors have been identified that play an important role in phosphatase activity. The catalytic subunits of PP1 and PP2A are promiscuous, displaying high activity and low substrate specificity, and are regulated by inhibitors specific to PP1 (DARPP-32, inhibitor 1/PP1) or PP2A (inhibitor 1/PP2A) [184, 185]. In contrast to PP1 and PP2, calcineurin activity is dependent on the association of calmodulin and Ca²⁺ with its regulatory domains. Specifically, Ca²⁺/calmodulin and Ca²⁺ bind to calcineurin, releasing the autoinhibitory domain from the active site and allowing substrate accessibility [186]. However, the association of immunophilins with immunosuppressive drugs, such as cyclosporin and FK-506, inhibits calcineurin activity [187].

The interplay of phosphatases, substrates, and inhibitors/activators is illustrated by the DARPP-32 integration of dopaminergic and glutaminergic signaling (Fig. 3.13) [188, 189]. As mentioned previously, DARPP-32 is a potent inhibitor of PP1. DARPP-32 activity is regulated by phosphorylation and dephosphorylation events that are dictated by the upstream signaling pathways of the D₁ receptor and NMDA receptor. D₁ receptor activation increases cAMP levels and in turn activates PKA. PKA phosphorylates DARPP-32 at Thr³⁴, converting it to a high-affinity inhibitor of PP1 [190]. Conversely, phosphorylation by cdk5 (cyclin-dependent kinase 5) at Thr⁷⁵ inhibits the PKA-dependent phosphorylation of Thr³⁴ and dampens the inhibitory effect of DARPP-32 on PP1 activity [191]. Calcineurin also plays a pivotal role in regulating the crosstalk between the dopamine and glutamate signaling pathways. Glutamate activation of NMDA receptor channels increases Ca²⁺ influx, providing a source of Ca²⁺

Figure 3.13 Crosstalk between signaling pathways. Following agonist stimulation, GPCRs can initiate diverse signaling pathways via coupling to different G proteins. Each of these G proteins has classical signaling molecules and corresponding downstream responses associated with it. In addition to these traditional pathways, G proteins can also regulate ion channels (Gβγ opening K⁺ channels) and proteins involved in RTK signaling (activation of Src to stimulate Ras and MAPK pathway).

for the activation of calcineurin. Once activated, calcineurin dephosphorylates DARPP-32 at Thr³⁴ and represses the DARPP-32-dependent inhibition of PP1 [192].

Regulated phosphorylation and dephosphorylation are fundamental events that control many cellular processes. It is therefore not surprising that aberrant/dysfunctional phosphorylation has significant physiological effects associated with a myriad of disease states that include cancer, diabetes, hypertension, and rheumatoid arthritis to mention a few. Many of the kinases and phosphatases discussed above are proposed to be suitable therapeutic targets. In fact, drugs such as Gleevec and Erlotinib that inhibit the tyrosine kinases ABL and the EGFR, respectively, have proven to be relatively successful in treating certain types of cancers [193, 194].

3.6 CONCLUSION

By interacting with GPCRs, RTKs, or ligand-gated ion channels, ligands are able to elicit a wide variety of responses through their signaling molecules, often in a cell-dependent manner. In recent years, the roles for many of these signaling molecules have been expanded to include novel functions. Examples of this includes the ability of second-messenger molecules, including AC and PLC β , to act as RGS proteins, thus regulating their own activity, and the capacity of certain RGS proteins to generate or alter cellular signals. Another occurrence of novel function is the ability of signaling molecules downstream of one type of receptor to communicate with receptors/signaling molecules in a separate pathway. This crosstalk has been demonstrated to occur across ion channels and GPCR signaling cascades (G $\beta\gamma$ regulation of ion flux) and between RTKs and GPCRs (G α activation of MAPK pathway, ARF interacting with GPCRs), as illustrated in Fig 3.13. Such a detailed level of intracellular communication provides a mechanism for tight control of cellular processes and responses to external stimuli. Additionally, several proteins have been determined to play a role in bringing second-messenger molecules together for novel downstream signals, including GRKs and RGS proteins, and much research is currently directed at determining the unique signals generated through interaction with these proteins. The dynamic interplay that exists between pathways adds heightened complexity and control to traditional signaling cascades and yields new insight into potential points of regulation within the cell for experimental manipulation and innovative therapeutic approaches.

Nicotinic acetylcholine receptors (nAChRs) are ligand-gated cation channels that when activated open, allowing sodium and calcium ions to flow into the cell and potassium ions to flow out of the cell, down their concentration gradients. This leads to depolarization of the membrane and an excitatory cellular response. These receptors are absolutely fundamental to physiology if for no other reason than that they mediate the fast, nearly fail-safe neurotransmission provided by acetylcholine at skeletal muscle and at virtually all autonomic ganglia, the adrenal gland, and sensory ganglia. Through these functions they influence virtually all organ systems in the body.

In addition to the critical physiological functions that nAChRs serve in the peripheral nervous systems, they are also found throughout the central nervous system (CNS), where, beyond their roles in mediating actions of endogenous acetylcholine, they are the targets for nicotine, the addictive agent in tobacco and

the main reason that people smoke (or at least the main reason so many have difficulty giving up smoking). In North America, about 50 million people smoke cigarettes regularly and the number is estimated to be *more than a billion worldwide*. Cigarette smoking is considered to be the most important preventable cause of early morbidity and mortality in most industrialized countries [1]; and if it exacts a lesser toll in developing countries it is probably only because the ravages of other health problems, such as famine, drought, poor nutrition, malaria, and other infectious diseases are, for the time being, more effective agents of depredation and premature death.

But obviously, nAChRs in brain did not evolve to mediate the stimulatory and addictive effects of nicotine; in fact, these receptors are widely distributed throughout the CNS, and they are frequently found on neurons of several major neurotransmitter systems. These strategic locations allow nAChRs to influence the release of dopamine, norepinephrine, acetylcholine, γ -aminobutyric acid (GABA), and glutamate (for a concise review of neurotransmitter release mediated by nicotinic receptors, see [2]). These neurotransmitters are, of course, associated with diverse effects, including arousal, reward, mood/affect, appetitive behaviors, neuroendocrine functions, and cognition. Thus, considering their effects on the CNS and the autonomic nervous system, neuronal nAChRs would be expected to influence multiple aspects of behavior, physiology, and the human condition. This chapter will review some of the fundamental aspects of these receptors, with emphasis on the different subtypes of neuronal nAChRs, their pharmacology, and their unusual regulation. For a review of nicotine addiction, see Chapter 15 in Volume II of this handbook.

4.1 BRIEF HISTORY OF nAChRs

It might seem a little unusual to begin an account of the contemporary neuropharmacology of a neurotransmitter receptor with its history, but it may be instructive to glimpse into the early studies of these receptors, in the years well before the advent of molecular biology, cloning strategies, ligand binding methods, patch clamp recordings, or, for that matter, most of the modern techniques that we rely on so heavily and more or less take for granted. The nicotinic receptors were the first receptors to be systematically explored, and their study laid the foundation for much of receptor biology. In fact, it was during studies of the actions of nicotine and the South American arrow poison curare on muscle that John Langley coined the term “receptive substance” [3, 4] and thus, along with Paul Ehrlich, who was studying antimicrobials and antigen–antibody interactions [5], developed the concept that small molecules such as hormones, antibodies, and exogenous chemicals (drugs) acted at specialized molecules on biological tissues. The receptor concept and theory led directly to the quantitative analyses of the actions of hormones, neurotransmitters, and drugs. But for many decades following the publications by Langley and Ehrlich, receptors were accepted, if at all, more as a concept than as actual biological entities that one day might be known in great detail. That was, of course, because many of the tools necessary to ask critical questions about receptors and probe their nature had not yet been developed.

The wide acceptance of nAChRs as more than a concept changed in the 1960s and early 1970s, especially after the isolation of nAChRs from the electric organ of fish and the demonstration of their function by Changeux and colleagues [6]. There

followed a series of detailed analyses of the molecular nature of nicotinic receptors from the electric organ of *Torpedo*, which laid the foundation for much of the understanding of nicotinic receptors at a molecular level three decades later (for reviews see [7–10]). Moreover, even though the receptors from electric organs are more similar to the mammalian muscle nAChR, their isolation and study led directly to the cloning of the neuronal nAChRs in mammalian brain and ganglia. The nAChR is now considered the prototype for the “Cys-loop” superfamily of ligand-gated ion channels, which includes GABA and glycine receptors as well as serotonin-3 receptors.

Our understanding of nAChRs has been greatly advanced by the clever use of certain natural products—indeed, probably no other biological molecule has been studied with so many unusual gifts of nature. The first recorded description by Europeans of the use of curare-tipped arrows by people of South America dates to the fifteenth century, but it is safe to say that the indigenous populations had used curare for its muscle-paralyzing actions in hunting and in defense long before the Europeans happened by (see [11] for an interesting account of early descriptions of curare use as related in the writings of fifteenth-century Spanish explorers). In the mid-nineteenth century, curare, which was isolated from crude plant sources, became an important tool in studies of muscle physiology. Notably, Claude Bernard used preparations of curare to block nicotine’s action when applied at the junction of nerve and muscle. Fifty years later, Langley would use these same two natural compounds to support the formulation of the receptor concept.

We move next to the 1937 World’s Fair in Paris, where David Nachmansohn, a biochemist studying nerve conduction and muscle contraction, chanced upon a demonstration of the power of an electric fish (*Torpedo marmorata*). Nachmansohn was interested in the bioenergetics of acetylcholine and acetylcholinesterase, the enzyme that hydrolyzes it, and he had recently learned that the fish electric organ was a kind of modified muscle. He began a series of studies that demonstrated that electric tissue of fish was extremely rich in acetylcholine and acetylcholinesterase, and he established that acetylcholine was in fact responsible for generating the electric charge (for a retrospective of the earliest studies of the cholinergic parameters of *Torpedo* electric tissue, see [12]).

The discovery of acetylcholine’s critical role in fish electric organs led 30 years later to the studies by Changeux and colleagues that resulted in the isolation of the prototypical nAChR from electric tissues; but these innovative studies required yet another critical gift from nature, this time from a snake. The venom of the Taiwanese banded krait, *Bungarus multicinctus*, contains a powerful toxin that paralyzes muscle. Chang and Lee [13] had isolated this protein and determined that it acted by potently and nearly irreversibly blocking the nicotinic receptors at the muscle end plate. They named it α -bungarotoxin, based on its position after electrophoretic separation. As related by Chang [14] in a brief retrospective, the isolation of α -bungarotoxin and elucidation of its mode of action did not attract much attention until Lee visited Changeux in Paris and provided him with a sample. Changeux, Lee, and their colleagues used the toxin to probe the nAChR in electric tissue [6] and eventually to purify the receptor [15].

Early studies of the nAChR purified from electric tissue revealed critical information about it, including the number of subunits in the receptor (four: α , β , γ , δ , with the α subunit represented twice, accounting for a pentameric structure), their partial

amino acid sequences, the flow of cations through the channel formed by the subunits, and the location of the acetylcholine binding site on the α subunits (reviewed in [7, 8, 16, 17]). The receptor has been imaged at 9 Å resolution in three-dimensional reconstructions from electron microscopy images [18] and more recently at 4 Å resolution [19]. Thus two molecules—proteins that for millions of years have provided their owners with means of survival—were brought together for the purpose of illuminating a fundamental question in biology and in fact contributed to the revolution in neurobiology that is still taking place. (It is unlikely that either the electric fish or the banded krait is aware of their critical roles in this.)

Beginning in 1982, several laboratories used cloning strategies to deduce the amino acid sequences of the α and γ subunits of the *Torpedo* electroplax receptor from their cDNA sequences [20–25]. And soon after, Numa and colleagues deduced the full amino sequences of all four subunits (α , β , γ , δ) from electroplax receptors [26, 27] as well as that for the α subunit of calf and human muscle ([28]; see [29] for a review). The amino acid sequences of the four subunits of electroplax are 40–65% identical, which suggests that they are the products of gene duplications over time. Moreover, the subunits seem to have been very good at what they do because they have been highly conserved across >400 million years of evolution, so that, for example, the 437 amino acids in the α subunit of *Torpedo* electric organ and human muscle differ by only $\sim 20\%$ [28, 30]. Knowing the sequences for the receptor subunits in electroplax provided a path toward understanding the neuronal nicotinic receptors. But there have been many surprises along the way.

4.2 NEURONAL nAChRs: OVERVIEW

The role of acetylcholine in autonomic ganglia neurotransmission has been known for most of the twentieth century (for an early review see [31]); and since the responses of ganglia to cholinergic nerve stimulation can be mimicked by application of nicotine, the receptors that mediate these responses are classified as nicotinic cholinergic, like the skeletal muscle. But early on it was recognized that certain drugs that potently block transmission at the neuromuscular junction are much less potent or even ineffective in blocking ganglionic transmission and vice versa. For example, it was noted that in a series of bis-methonium compounds containing identical quaternary nitrogen groups at each end but separated by a variable number of simple methylene groups, that is, $(-\text{CH}_2-)_n$, the number of methylene groups determines whether a compound is a potent blocker of ganglia or of muscle [32]. Hexamethonium, the compound containing six methylene groups, effectively blocked ganglia, while decamethonium effectively blocked muscle. Since the only difference between these two compounds is the number of carbon atoms in the methylene chain that separates the two positively charged methonium head groups, the difference in potency was thought to reflect the topology of the receptors in the ganglia and muscle, specifically the distances between anionic groups on the receptor that could accommodate the two cationic groups of the blocking drugs [33]. It is now thought that while the distance between the anionic groups is one determinant, it is not the only one.

Despite these differences, the genes coding for the receptors in the nervous system proved to be similar enough to the muscle-type receptor genes to allow hybridization to the muscle subunit cDNA probes under low-stringency conditions. Thus, having

the cDNA for the subunits of the electrophysiological and mammalian muscle receptor allowed the isolation and cloning of multiple receptor subunit genes in the nervous system. That initial strategy was well rewarded, and since the isolation of the subunits from neuronal tissues and the location of their mRNA in rat brain [34–39], nine different α subunits ($\alpha 2$ – $\alpha 10$) and three different β subunits ($\beta 2$ – $\beta 4$), all distinct from the muscle receptor subunits, have been found in vertebrate neuronal tissues (for several excellent and comprehensive reviews on the diversity of the neuronal nicotinic receptors, see [40–43]).

4.3 STRUCTURE OF nAChRs

Many of the salient structural characteristics of nAChRs have been derived from years of elegant studies of vertebrate receptors (for several excellent detailed reviews see [9, 19, 42, 44]), and recently our understanding of many of these structural features has been reinforced and some new ones revealed by X-ray crystallography of a molluscan acetylcholine binding protein that resembles the amino terminal of the $\alpha 7$ subunit [4, 5].

All subunits consist of a polypeptide chain with a relatively large hydrophilic amino terminal followed by four hydrophobic transmembrane domains, designated M1–M4, and a relatively short C-terminus (Fig. 4.1). A large intracellular loop formed between M3 and M4 in all of the subunits contains the most variable sequences. The extracellular N-terminus contains a disulfide bond formed by two cysteines separated by 13 amino acids. This cys loop is common to all nAChR subunits, as well as to the subunits of the GABA_A, GABA_C, glycine, and serotonin-3 receptors, giving this receptor superfamily its name. Like the muscle receptor, the neuronal nAChRs are composed of five subunits assembled around a central ion channel so that their M2 transmembrane domains and a portion of the M1 domains line the channel (Fig. 4.1b) and contribute to the ion gating mechanism and probably to the state of the channel. Different combinations of the 12 α and β neuronal subunits comprise the pentameric receptors (Fig. 4.1c) and define its subtype.

The amino acid sequences of the subunits designated as $\alpha 2$ – $\alpha 10$ all have ~50% homology with the muscle $\alpha 1$ subunit overall, but the homology is much greater in the membrane-spanning regions [40]. All neuronal α subunits have in common with the $\alpha 1$ subunit of muscle a second disulfide bond formed from adjacent cysteine amino acids at or near positions 192–193 in the sequence. This disulfide bond exerts a powerful influence on the binding site for acetylcholine and other agonists [46–49], and in fact it is a major criterion for belonging to the α -subunit class. There is less sequence homology between the neuronal $\beta 2$ – $\beta 4$ subunits and the $\beta 1$ subunit of muscle or even among the neuronal β subunits themselves [40, 41]. The acetylcholine binding site is formed at the interface of an α subunit and an adjacent subunit; however, as will be described below, not all α and β subunits are equal in this regard.

When certain combinations of α and β subunits are expressed in heterologous systems, such as *Xenopus* oocytes or mammalian cell lines, they can form nAChR agonist binding sites and functional channels that represent potential nAChR subtypes. Examples of generic nAChR subtypes are shown in Figure 4.1c. Although all of the subtypes conduct Na⁺, K⁺, and Ca²⁺, their channel and pharmacological properties can vary considerably, as does their regulation during exposure to

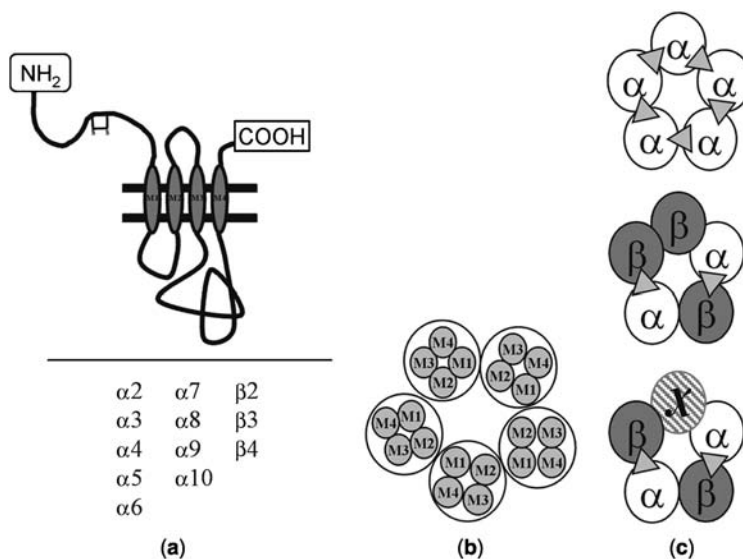

Figure 4.1 Basic structure of neuronal nAChRs. (a) Neuronal nAChRs are pentameric proteins composed of five subunits from among nine α and three β subunits. Each subunit consists of a large N-terminus of ~ 210 amino acids, four transmembrane domains designated M1–M4, and a short C-terminus. A large cytoplasmic loop forms between M3 and M4 of all subunits and contains the most variable sequences among the different subunits. The extracellular amino terminal contains a disulfide bond formed by two cysteines separated by 13 amino acids. This Cys-loop is common to all nAChR subunits, as well as to the GABA_A, GABA_C, glycine, and serotonin-3 receptors. A second disulfide bond, formed from adjacent cysteine residues at about positions 192–193, close to the first transmembrane segment, is common to all α subunits and exerts a strong influence on the agonist binding site. (b) The M2 and a portion of the M1 transmembrane segments of each subunit line the channel and contribute to its ion selectivity. In addition, the different states of the channel—open, closed, desensitized—are probably executed here by an allosteric mechanism. (c) Neuronal nAChR subtypes can be homomeric receptors, comprised of $\alpha 7$, $\alpha 8$ or $\alpha 9$ subunits only; simple heteromeric receptors, comprised of combinations of one type of α and one type of β subunit; or *mixed* heteromeric receptors, comprised of one or more types of α subunit combined with one or more types of β subunit.

nicotine. Most of the known nAChR subtypes are heteromeric—that is, they are composed of combinations of α and β subunits. Simple heteromeric receptors are formed from a single type of α subunit combined with a single type of β subunit—for example, $(\alpha 4)_2 (\beta 2)_3$. *Mixed* heteromeric receptors contain one or more types of α subunit combined with two or more types of β subunit, or vice versa. Some of the nAChRs in chick ciliary ganglia are mixed heteromeric receptors composed of $\alpha 3$, $\alpha 5$ and $\beta 4$ subunits, presumably $(\alpha 3)_2 (\alpha 5)(\beta 4)_2$ [50, 51], and several different mixed heteromeric subtypes have been found in some CNS regions from chick [52, 53] and rat [54–57], which in some cases contain receptors with up to four different subunits.

The $\alpha 7$, $\alpha 8$, and the $\alpha 9$ subunits can form homomeric receptors composed of five identical α subunits without the need for a β subunit. In particular, the $\alpha 7$ subunit forms a homomeric receptor that is highly represented in the CNS and has been implicated in a variety of synaptic and extra synaptic functions. It is the most widely

distributed and the most widely studied of the homomeric receptors (for reviews see [58, 59]. The $\alpha 8$ subunit has so far been found only in avian species. The $\alpha 9$ subunit has a very limited distribution, but it appears to associate with α_{10} subunits to form a nAChR in cochlear hair cells [60]. Interestingly, these receptors have recently been implicated in the ototoxicity that has long been associated with the antimalarial compounds quinine quinidine, and chloroquine [61].

The rules of assembly for the α and β subunits are not completely known; therefore, the number of receptor subtypes that actually exist in the vertebrate nervous system is not known. However, a few important “rules” have emerged from studies of subunit combinations expressed heterologously in oocytes or in mammalian cells. These rules are helpful in thinking about the potential diversity of the neuronal nAChRs in native tissues and in assigning subtypes to particular functions or locations. Thus, the rules of assembly established so far are as follows:

1. The $\alpha 2$, $\alpha 3$, $\alpha 4$, and $\alpha 6$ subunits require association with either $\beta 2$ or $\beta 4$ subunits to form functional ligand-gated ion channels, and, based on the muscle receptor stoichiometry, the neuronal receptors are thought to contain at least two α subunits.
2. The $\alpha 5$ subunit requires association with other α subunits as well as $\beta 2$ or $\beta 4$ subunits to form a functional receptor or agonist binding site [62, 63]. Similarly, the $\beta 3$ subunit requires both other β subunits as well as other α subunits to form a receptor [64]. Thus, the presence of either the $\alpha 5$ or the $\beta 3$ subunit indicates that a receptor is a mixed heteromeric subtype.
3. As stated above, the $\alpha 7$, $\alpha 8$, and $\alpha 9$ subunits can each form homomeric receptors, and $\alpha 9$ can also associate with α_{10} to form a nAChR with unusual properties [60].

The full subunit composition of neuronal nAChR subtypes in most tissues is not yet known; therefore, when a receptor subtype in a tissue is tentatively identified by its pharmacological or biophysical characteristics, the convention of adding an asterisk has been adopted to signify that it may have one or more additional subunits [65]. For example, $\alpha 3\beta 4^*$ would designate receptors that are composed of $\alpha 3$ and $\beta 4$ subunits, but one or more other subunits might also be incorporated in at least some of the receptors, for example, $\alpha 3\beta 4\alpha 5$.

4.4 PHARMACOLOGY OF MAJOR NEURONAL nAChR SUBTYPES

As described above, the physiology and to some extent the pharmacology of nAChRs in ganglia and adrenal gland have long been recognized and studied. In fact, several early antihypertensive drugs, such as hexamethonium and mecamylamine, were aimed at nAChRs in autonomic ganglia. These nAChR blockers lowered blood pressure (sometimes quite dramatically) by blocking the signals at the ganglia that control blood vessel tone via postganglionic sympathetic axons that release norepinephrine; but because these drugs block signals at *all* autonomic ganglia, they also produce a wide range of unacceptable but entirely predictable side effects. Since

there are now many drugs that lower blood pressure via several more subtle and scalable mechanisms, ganglionic nAChR blockers are seldom if ever used clinically.

It is curious that, except for the recognition that the recurrent collateral inhibition of spinal motor neurons involves nAChRs on the inhibitory Renshaw interneuron, there seems to have been very limited exploration of the role of nAChRs in the CNS until the early 1970s. This despite the fact that during a large part of the twentieth century a significant fraction (up to 50%) of the adult populations of the United States, Canada, and most European nations smoked cigarettes. The biological underpinnings for this behavior, even in the face of the well-known health risks of smoking, was a subject of some conjecture. One intriguing finding, however, was that nicotine could release dopamine and norepinephrine from rat brain slices [66–69]; and the possible connection between these catecholamines and other stimulant drugs was already widely suspected [70].

4.4.1 The $\alpha 7$ nAChR

Studies in the 1970s established the existence of binding sites for [125 I] α -bungarotoxin ([125 I] α -BTx) in mammalian brain. These sites were at first thought to be similar to the muscle nAChR, but we now know these receptors as the homomeric $\alpha 7$ nAChR subtype, which are structurally quite different from the muscle receptor. Because it is essentially the only nAChR in mammalian brain that binds α -BTx with high affinity, the homomeric $\alpha 7$ receptor can be located and measured definitively in binding studies [49, 71, 72]. Interestingly, early studies found that α -BTx, which you will recall blocks the muscle nAChRs very potently and nearly irreversibly, did not block responses evoked by acetylcholine or nicotine in some neuronal cells, such as PC12 cells (a rat neuroendocrine cell) and rat and chick sympathetic ganglia [73–75].

The failure of α -BTx to block acetylcholine-stimulated responses in neuronal tissues led to some early speculation that the [125 I] α -BTx binding site might not represent a nicotinic cholinergic receptor. Moreover, because homomeric $\alpha 7$ nAChRs desensitize rapidly upon application of agonists, they were difficult to measure with earlier patch clamp techniques. But since then, the introduction of fast application methods for patch clamp recording has allowed extensive studies of these receptors in heterologous expression systems as well as in neuronal tissues. The $\alpha 7$ receptor is notable for its large calcium conductance, which equals that of N-methyl-D-aspartate (NMDA) receptors [76, 77]. In part because they are often found outside the zones of synaptic specialties and because of their high calcium permeability, the $\alpha 7$ receptors have been implicated in a variety of neuronal functions, including “perisynaptic” as well as postsynaptic and presynaptic mediation of cholinergic signals (see [59] for a review).

Measurements of $\alpha 7$ receptors in mammalian brain can be made definitively with [125 I] α -BTx, and the pharmacology of the $\alpha 7$ receptor binding site in rat and mouse brain has been well studied [49]. However, there is sometimes significant disparity in the affinities reported for α -BTx in different studies, which is probably related to the different assay systems used in the studies (e.g., brain vs. heterologous expression systems) and the different methods used by various laboratories. In addition, in some cases the difference might derive partly from uncertainty of the specific radioactivity of the [125 I] α -BTx used and consequent uncertainty in the actual concentration of the radioligand used in the competition studies. Thus two- to five-fold differences in K_i

values derived from a logscale for the same drug are not uncommon. Nevertheless, there is good agreement on the rank order of drug affinities measured in different laboratories. Table 4.1 compares the K_i values for several drugs competing with [125 I] α -BTx for binding at $\alpha 7$ receptors measured in rat brain membranes with values measured at human $\alpha 7$ receptors heterologously expressed in SH-EP1 cells (a human epithelial cell line). The rank order and even the K_i values measured in the two studies are in general agreement, especially considering again that the measurements are from different laboratories derived with somewhat different methods. However, the difference in binding values for α -BTx itself is notable, so it will be important to learn if the difference in affinity of α -BTx accurately reflects an actual difference between the rat and human receptor or is related to differences in the processing of the receptors in native tissues and the heterologous expression system.

In measurements of function by whole-cell patch clamp recordings, acetylcholine, nicotine, and cytisine are full agonists in both chick $\alpha 7$ receptors expressed in oocytes [78, 79] and human $\alpha 7$ receptors expressed in mammalian cells [80, 81]. Interestingly, choline, the precursor to acetylcholine in its synthesis as well as a product of acetylcholine hydrolysis after its release, is an agonist at $\alpha 7$ receptors [81, 82]. As is the case for virtually all nAChRs, the potencies of agonists to activate $\alpha 7$ receptor channel function is significantly lower than their affinities measured in binding assays would have predicted (i.e., agonist EC_{50} values are much higher than their K_i values). This reflects the difference in the receptor conformation in its resting state, from which it can be activated, and its desensitized state, which binds agonists with much higher affinity but is essentially nonactivatable. Interestingly, 1,1-dimethyl-4-phenylpiperazinium (DMPP) appeared to be a very weak agonist ($\sim 5\%$ compared to nicotine) at the chick $\alpha 7$ receptor expressed in frog oocytes [78, 79] but nearly a full agonist at human $\alpha 7$ receptors expressed in mammalian cells [80]. Again this could be due to the different origins of the receptor or the cell type in which it was expressed.

TABLE 4.1 K_i Values of Drugs Binding at $\alpha 7$ nAChRs from Rat Brain and at Human $\alpha 7$ nAChRs Expressed in SH-EP1 Cells

Drug	K_i (nM)	
	Rat Brain $\alpha 7$	Human $\alpha 7$ Cells
Agonists		
Acetylcholine	4,000	—
Nicotine	820	420
Cytisine	1,400	380
Carbamylcholine	12,000	3,500
DMPP	470	40
Antagonists		
<i>d</i> -Tubocurarine	2,800	3,000
α -BTx	0.16	7
Methyllycaconitine	1.1	14

Note: Data for rat $\alpha 7$ receptor from [49], except methyllycaconitine, which are from [77a]. Data for human $\alpha 7$ receptor from [77b].

4.4.2 Heteromeric nAChRs

The suspicion early on that the [125 I] α -BTx binding sites might not represent the only neuronal nAChR led to a search for other brain nicotinic binding sites with characteristics that could be related to nAChRs. In 1979 and 1980, three papers reported [3 H]nicotine binding sites in brain [83–85]. These sites had many of the pharmacological characteristics expected of a nicotinic receptor, but α -BTx did not compete effectively for them. A short time later studies using [3 H]acetylcholine [86] and [3 H]nicotine [87] added further evidence that that these binding sites in brain probably represented the agonist recognition sites of a neuronal nAChR. Moreover, not only was α -BTx an ineffective competitor for the binding sites labeled by these agonists but the brain distributions of the high-affinity agonist binding sites and the α -BTx binding sites were markedly different, indicating that they were not even part of the same receptor molecule [72, 86, 87]. These studies were thus a strong indication that there is more than one type of nAChR in brain. Interestingly, the studies with the agonist radioligands found that several effective classical antagonists of ganglionic nAChRs, such as mecamylamine and hexamethonium, do not compete effectively for [3 H]acetylcholine and [3 H]nicotine binding sites. That is because these and several other ganglionic antagonists act primarily by blocking the receptor channel, rather than by competing for the agonist binding site [88, 89].

Later studies established that the brain binding site for the [3 H]-agonist ligands, as well as that for [125 I] α -BTx, depended on an intact disulfide bond that could be reduced and reoxidized with corresponding loss and restoration of agonist binding [48, 49]. This requirement for an intact disulfide bond in brain nAChR binding sites is similar to that in electroplax and muscle nAChRs [46, 47], and in fact, it appears to be a common feature of the agonist recognition site of all nAChRs.

[3 H]Acetylcholine and [3 H](–)nicotine label the same receptor sites in rat and mouse brain [49, 90]; importantly, however, neither is an effective ligand for labeling and measuring neuronal nAChRs in autonomic ganglia, adrenal gland, or PC12 cells, all of which are known to contain nAChRs—indeed, these receptors mediate the primary functions of autonomic ganglia and adrenal chromaffin cells. In the early 1990s, studies with [3 H]cytisine established it as an excellent radioligand for measuring nAChRs in brain [91–94]. It has 10–20 times higher affinity than [3 H]acetylcholine or [3 H](–)nicotine and low nonspecific binding (which translates into a better signal-to-noise ratio). But even this ligand was ineffective for measuring neuronal nAChRs in ganglia and PC12 cells. The reasons that these radioligands were unable to measure neuronal nAChR binding sites in ganglia and PC12 cells became apparent when the pharmacology of the predominant receptor subtypes in these tissues was better understood and the narrow spectrum of all of these radioligands was realized.

Rat brain expresses the genes for nearly all of the nAChR α and β subunits [40, 95]. The mRNA transcripts have different distributions, but there is extensive overlap among some of them. For example, the $\alpha 4$ and $\beta 2$ subunit mRNAs overlap in most brain regions [37] and the $\alpha 3$ and $\beta 4$ subunit mRNAs overlap in many brain areas [96]. There is sometimes a significant mismatch between the location of subunit mRNA and its cognate protein. There may be several reasons for this mismatch, but one important factor is that neuronal nAChRs are often found on axons and axon terminals some distance from the cell bodies, where mRNA is typically concentrated. Fortunately, the development of nAChR subunit-selective antibodies has provided

critical probes to measure the specific subunits in the nervous system ([97–103]; for a review, see [104]). Moreover, these antibodies have provided tools to determine the subunit composition of different heteromeric neuronal nAChR subtypes and have thus allowed major subtypes, defined by their subunit composition, to be identified in several areas of the nervous system. For example, using antibodies, the predominant nAChR in rat and chick forebrain was determined to be the $\alpha 4\beta 2$ subtype [52, 105, 106]. In contrast, in the ganglia that have been studied the $\alpha 4\beta 2$ subtype exists at low levels, if at all, and the major, though not the only, nAChR appears to be an $\alpha 3\beta 4^*$ subtype [62, 107, 108].

Studies of nAChR activation in oocyte expression systems had established clear differences in the pharmacology of receptors that contain $\beta 2$ versus $\beta 4$ subunits [109–111], but the inability to radiolabel and measure nAChRs in ganglia was perplexing, and, more important, it was a significant obstacle to delineating the pharmacology of the diverse members of the neuronal nAChR family and exploring their roles and regulation. Moreover, it was apparent that if the [^3H] agonists in use at the time did not label the receptor subtype(s) in ganglia and PC12 cells, they probably did not label these subtypes if they existed in the CNS either.

The solution to this problem came in the form of yet another gift from nature, the discovery of which is itself a fascinating story. As detailed by Daly [112, 113] and summarized here, in the mid-1970s Daly and colleagues extracted an alkaloid from the skin of a small Ecuadoran poison dart frog, *Epipedobates tricolor*. When injected into mice the extract elicited a Straub-tail response, which is usually indicative of opioid-like activity. Thus the alkaloid was of interest as a possible analgesic. Indeed, further studies with about 500 μg of the purified alkaloid isolated by column chromatography showed it to be ~ 200 times more potent than morphine in preclinical tests of analgesic activity. But surprisingly, the analgesic activity was not blocked by naloxone, a potent opioid antagonist. Clearly this alkaloid was potentially very important and of great interest. Unfortunately, in the years between the alkaloid's initial discovery by Daly and colleagues and its subsequent isolation several years later, the source of this important and mysterious alkaloid all but disappeared. Studies on extracts from *E. tricolor* subsequently collected in Ecuador showed they had very low levels of the active alkaloid, and specimens of *E. tricolor* that had been brought out of Ecuador and raised in the United States did not produce any of the material. It is now thought that the alkaloid of interest was a product of the frogs' diet in their indigenous habitat. Daly waited until 1990, when he thought that the necessary analytical techniques had become sensitive enough to solve the structure of the alkaloid from the small amount of the original sample he had wisely held back. The gamble with the world's entire supply of the active material worked and the structure of epibatidine, the active alkaloid, was published in 1992 [114]. Within two years of the publication of its structure, no fewer than eight laboratories published synthesis schemes [115].

Studies with the new supplies of synthesized epibatidine revealed more remarkable features. Epibatidine's potent analgesic activity in mice was blocked by the noncompetitive nicotinic antagonist mecamylamine [112, 113], indicating that it is an agonist. Moreover, it displayed very high affinity ($\sim 50\text{ pM}$) for heteromeric neuronal nAChRs labeled by [^3H](–)nicotine in rat brain. The high affinity of epibatidine in binding studies paralleled its agonist potency in functional studies, although like all nicotinic agonists that have been studied, its affinity for its receptors

as measured by its dissociation constant (K_i or K_d) in binding studies is 50 to 300 times higher than its potency (EC_{50}) in functional studies.

In 1994, [3H]epibatidine ([3H]EB) was developed as a ligand to measure nAChRs, and studies with it quickly revealed that it labeled not only the heteromeric nAChRs in brain but also those in adrenal gland and retina; furthermore, it displayed very low nonspecific binding over a wide concentration range [116–118]. The affinities of [3H]EB for its binding sites in brain and ganglionic tissues were found to be ~ 50 and 300 pM, respectively, a hint of the marked differences in the pharmacology of the receptors in these two tissues. Epibatidine, which contains a chlorine atom in its ring structure, can also be synthesized with an iodine and still retain high affinity for nAChRs [112]. [^{125}I]EB has since been synthesized [119] and has proven to be particularly useful for measuring nAChRs in tissues that are in limited supply or with a low density of receptors, and especially for mapping nAChRs in autoradiography studies, where exposure times can be decreased from the several weeks often required with [3H]EB to one to four days [120, 121].

4.4.2.1 Pharmacology of Simple Heteromeric nAChRs. Ligand binding studies with [3H]EB have helped to elucidate the pharmacology of the diverse subtypes of nAChRs in the nervous system. For example, [3H]EB binds with high affinity to each of six different simple heteromeric rat nAChR subunit combinations expressed in oocytes [122] and in mammalian cells [123]. This has allowed the pharmacological profiles of the binding sites for these possible receptor subtypes to be clearly delineated. Table 4.2 shows the pharmacology of these binding sites expressed in the mammalian cells, but the pharmacological profiles of the receptors expressed in oocytes are similar. These comparative studies across subunit combinations showed that, in general, all of the nicotinic agonist drugs examined have higher affinity for combinations formed with the $\beta 2$ subunit than with the $\beta 4$ subunit. In particular, acetylcholine, nicotine, and cytosine, all of which were among the earliest radiolabeled ligands for nAChRs, display a dissociation constant (K_i) for the $\alpha 3\beta 4$ subunit combination of 200 nM or greater. This translates into an affinity that is far too low to reliably radiolabel receptors comprised of this subunit combination, which explains why these ligands are not very useful as radioligands for the nAChRs in ganglia.

A-85380, a pyridyl ether compound synthesized and characterized at Abbott Laboratories [124, 125], discriminates particularly well between nAChRs containing $\beta 2$ and $\beta 4$ subunits. In fact, it and its iodinated analog, 5-iodo-A-85380, display 50- to >1000 -fold higher affinities at the $\beta 2$ -containing subunit pairs than the $\beta 4$ -containing pairs (Table 4.2). Importantly, this selectivity extends to comparisons between the $\alpha 4\beta 2$ subunit combination, which represents the predominant receptor in brain, and the $\alpha 3\beta 4$ combination, which represents the predominant receptor in many autonomic ganglia.

Earlier studies measuring current responses in oocytes expressing α and β subunit pairs demonstrated that both subunits influence the sensitivity of nAChRs to agonist drugs [109]; and although the β subunit seems to exert the major effect on the binding site pharmacology, the α subunit also clearly influences the binding site pharmacology. For example, several agonists have a slightly higher affinity for the $\alpha 4\beta 2$ than for the $\alpha 3\beta 2$ subunit combination; but cytosine in particular displays a marked difference, which has helped to tentatively identify the relatively few populations of $\alpha 3\beta 2^*$ receptors in the rodent brain [121, 126]. Similarly, the much higher affinity of A-85380

for $\beta 2$ -containing nAChRs compared to $\beta 4$ -containing nAChRs makes it useful as a pharmacological mask of the $\beta 2$ receptors, which has allowed the location and relative density of several clusters of $\beta 4$ -containing receptors (probably $\alpha 3\beta 4^*$ receptors) labeled by [125 I]EB in rodent brain to be mapped [121, 127] (see below).

As with any model system, the pharmacological profiles of these subunit combinations in heterologous systems are useful only to the extent that they reflect native nAChRs. Table 4.3 compares the binding affinities of drugs at heterologously expressed subunit combinations with native receptors in rat forebrain, which are predominantly the $\alpha 4\beta 2$ subtype, and pineal gland, which expresses the $\alpha 3\beta 4$ subtype virtually exclusively [128]. The close agreement between the values for the heterologously expressed subunit combinations and the native nAChRs from rat tissues provides a measure of confidence that the pharmacology of the binding sites in heterologous expression systems reliably represents the pharmacology of the binding site of the native receptors. Interestingly, the affinities of many of these drugs at the rat $\alpha 4\beta 2$ subunit combination appear to be lower than those at the human $\alpha 4\beta 2$ subunit combination expressed in SH-EP1 cells [129], but both the rank order and the relative affinities of the drugs in the two systems are very similar.

Activation of nAChR in heterologous expression systems has been studied in several ways. The most widely used method is whole-cell patch clamp recordings of subunit combinations expressed in oocytes [109, 110, 130, 131] or in mammalian cell lines [132–137]. In addition to whole-cell recordings in mammalian cells, nAChR function has been assessed using measurements of $^{86}\text{Rb}^+$ efflux through the receptor channel [129, 138–140] and measurements of fluorescence linked to changes in membrane potential and/or intracellular calcium [141, 142]. Whole-cell patch clamp recordings are very sensitive and provide real-time, direct measurements of physiological responses, while ion flux and fluorescence-based assays allow relatively rapid comparisons across nAChR subunit combinations and among drugs.

^aNote: The native receptors in the rat forebrain are predominantly an $\alpha 4\beta 2$ subtype and those in rat pineal gland are nearly exclusively the $\alpha 3\beta 4$ subtype.

Data for $\alpha 4\beta 2$ subunits and rat forebrain adapted from [123]; data for $\alpha 3\beta 4$ subunits and pineal gland from [128].

Considering the different expression systems and measurements that have been used to assess the pharmacology of functional responses, it is not surprising that there is less agreement in the EC_{50} values than in the binding site K_i values for drugs across various nAChR subunit combinations, or even at any one subunit combination. There is, however, agreement on several important points:

1. Most nicotinic agonists are more potent at heterologously expressed $\alpha 4\beta 2$ nAChRs than at $\alpha 3\beta 4$ receptors. An example of this can be seen in Table 4.4, which compares agonist-stimulated $^{86}\text{Rb}^+$ efflux in cells expressing the human $\alpha 4\beta 2$ receptor [129] and the rat $\alpha 3\beta 4$ receptor [140]. The difference in potency at these two receptor subtypes parallels the higher binding affinity of agonists for the $\alpha 4\beta 2$ receptors.
2. Cytisine is a weak partial agonist at $\beta 2$ -containing receptors, eliciting only 10%–40% of the response stimulated by acetylcholine or nicotine; in contrast, it is nearly a full agonist at $\alpha 3\beta 4$ receptors. The low efficacy of cytisine at $\beta 2$ containing nAChRs was first noted in oocyte studies [109, 110] and has also been a consistent finding in $\alpha 4\beta 2$ receptors expressed in mammalian cells. It is an important feature that can help to determine whether a nicotinic response in native tissues is mediated by a nAChR containing $\beta 2$ or $\beta 4$ subunits.
3. DMPP usually appears to be a partial agonist with $\sim 70\%$ efficacy at the heterologously expressed $\alpha 4\beta 2$ receptor subtype [129, 138] as well as at the $\alpha 3\beta 4$ receptor subtype [140].
4. Epibatidine is the most potent agonist currently known. Furthermore, it sometimes appears to have greater efficacy than acetylcholine or nicotine. This greater efficacy probably results from its ability to elicit a full agonist

TABLE 4.4 Comparison of EC₅₀ Values of Nicotinic Agonists to Stimulate ⁸⁶Rb⁺ Efflux Through Human $\alpha 4\beta 2$ nAChRs Expressed in SH-EP1 Cells [129] and Rat $\alpha 3\beta 4$ nAChRs Expressed in HEK293 Cells [140]

DMPP	1.9	28

response at concentrations well below those that begin to block the receptor channel, whereas, in contrast, less potent agonists appear to produce some channel blockade even within the concentration range necessary to measure their full activation of receptors.

5. Mecamylamine and hexamethonium, classic ganglionic blockers, appear to act noncompetitively by blocking the nAChR channel, rather than by competing for the agonist recognition site.
6. Dihydro- β -erythroidine (DH β E), in contrast to the classic ganglionic blockers, is a competitive antagonist, and like agonists, it is more potent at $\alpha 4\beta 2$ receptors than at $\alpha 3\beta 4$ receptors.

Again, because essentially all of the nAChRs in the rat pineal gland are the $\alpha 3\beta 4$ subtype, it has provided a good tissue in which to compare the functional responses of native and heterologously expressed receptors. As shown in Table 4.5, the EC₅₀ values for nicotinic drugs to activate whole-cell currents via $\alpha 3\beta 4$ nAChRs in rat pineal cells in primary culture are very similar to the values to activate ⁸⁶Rb⁺ efflux through $\alpha 3\beta 4$ nAChRs heterologously expressed in HEK293 cells. Thus, despite the very different methods used to assess receptor-mediated responses, the potency of a drug to activate the heterologously expressed $\alpha 3\beta 4$ receptors provides an accurate measurement of its potency at native receptors. Moreover, DMPP, which is a partial agonist at heterologously expressed $\alpha 3\beta 4$ receptors, is also a partial agonist at the $\alpha 3\beta 4$ receptors in the rat pineal gland [128].

Comparisons between native and heterologously expressed receptor subtypes are limited because there are so few native tissues that contain a preponderance of any one nAChR subtype. The $\alpha 4\beta 2$ subtype is the predominant heteromeric nAChR in most of the rat forebrain [105, 106], and it appears to be required for nicotine self-administration in mice [143–145]. The $\alpha 3\beta 4$ receptor appears to be the predominant nAChR in several autonomic ganglia, the trigeminal ganglia [107], the pineal gland [128], and certain areas of the brain [121, 126, 146]. Heterologous expression systems have provided an important tool with which to explore these two simple heteromeric nAChRs in some depth, and the differences in the pharmacological characteristics and functional properties between them are becoming well delineated.

4.4.2.2 Pharmacology of Mixed Heteromeric nAChRs. The properties of mixed heteromeric nAChRs are less well defined because their more complex subunit structure presents an inherent challenge to their study. For example, the number of receptor subtypes possible in a cell increases exponentially with the number of subunits present. Moreover, no native tissue is known that expresses a single mixed heteromeric subtype exclusively or even predominantly, and cell lines that stably express a single mixed heteromeric receptor exclusively are just now being developed. Nevertheless, some progress has been made in delineating the pharmacology of some mixed heteromeric receptors.

1. *Receptors Containing $\beta 2$ and $\beta 4$ Subunits* Mixed heteromeric nAChRs with the subunit composition of $\alpha 3\beta 2\beta 4$ can be expressed in oocytes and seem to have hybrid properties of $\alpha 3\beta 2$ and $\alpha 3\beta 4$ receptors [111]. Thus, cytisine is a full agonist, as it is in $\alpha 3\beta 4$ receptors, but the receptors are also sensitive to blockade by neuronal bungarotoxin (κ -toxin), another toxin isolated in small quantities from the venom of *B. multicinctus* [147, 148], which appears to be selective for nAChRs containing the $\alpha 3\beta 2$ subunit pair [149].

2. *Receptors Containing $\alpha 5$ Subunits* The $\alpha 5$ subunit in combination with any β subunit does not support channel function or even form an agonist binding site. Therefore, any nAChR that contains $\alpha 5$ subunits would have to also contain another α subunit as well as a β subunit— that is, it would be a mixed heteromeric (see rules of assembly, above). The $\alpha 3\beta 4\alpha 5$ subtype is found in chick ciliary ganglia [50, 62] and in rat superior cervical ganglia, where $\sim 30\%$ of the receptors are $\alpha 3\beta 4\alpha 5$ [108, 150]. Most of the heteromeric nAChRs in chick brain appear to be the $\alpha 4\beta 2$ subtype, but a small fraction ($\sim 15\%$) also contain the $\alpha 5$ subunit [52]. Similarly, most of the nAChRs in rat brain are the $\alpha 4\beta 2$ subtype, but some of these also contain the $\alpha 5$ subunit. Thus, in the rat cerebral cortex $\sim 12\%$ of the $\alpha 4\beta 2$ receptors appear to contain the $\alpha 5$ subunit, whereas in the hippocampus this subunit is found in $\sim 30\%$ of the $\alpha 4\beta 2$ receptors (unpublished).

The presence of the $\alpha 5$ subunit does not appear to markedly affect the nAChR binding site pharmacology [52, 151], but it does alter responses to certain drugs. Thus, deletion of the $\alpha 5$ subunit by antisense oligonucleotide treatment

appears to increase the sensitivity of receptors in chick sympathetic ganglion neurons to acetylcholine, nicotine, and cytisine [152]. On the other hand, inclusion of $\alpha 5$ subunits in $\alpha 3\beta 2$ receptors expressed in oocytes increased their sensitivity to acetylcholine but not to other agonists [153]. Furthermore, the presence of the $\alpha 5$ subunit appears to increase the rate of nAChR desensitization [63, 151, 153]. These effects, combined with the possibility that the $\alpha 5$ subunit affects the trafficking and thus the cellular destination of nAChRs in ganglion neurons [154], suggest that the $\alpha 5$ subunit may significantly influence the physiology as well as the pharmacology of nAChRs. Moreover, recent studies suggest that the presence of the $\alpha 5$ subunit affects the regulation of nAChRs during chronic treatment with nicotine [155].

3. Receptors Containing $\alpha 6$ Subunits Studying potentially important mixed heteromeric nAChRs set among several other, often more numerous, nAChRs is challenging. The $\alpha 6$ -containing receptors are an example of such receptors. The $\alpha 6$ subunit mRNA is expressed in several important and interesting regions in rat brain, including in nuclei of dopamine and norepinephrine neurons [156], which have long been associated with nicotine-stimulated behaviors related to reward responses and locomotion. High levels of this mRNA are also expressed in chick retina [157].

Studies of the $\alpha 6$ receptors have been aided enormously by the use of α -conotoxin MII, one of many small conotoxin peptides discovered in the venoms of predatory marine snails (genus *Conus*). The α -conotoxin group of peptides targets nAChRs with remarkable specificity (for a review, see [158]), and one of these, α -conotoxin MII, has high affinity for $\alpha 6\beta 2^*$ and $\alpha 3\beta 2^*$ nAChRs [159]. Although, it was initially thought to be selective for $\alpha 3\beta 2^*$ receptors, subsequent studies using knockout mice lacking the $\alpha 6$ subunit gene indicate that the $\alpha 6\beta 2^*$ subtype is its most likely target in most brain areas [160]. Early studies with α -conotoxin MII showed that it blocked 30–50% of nicotine-stimulated dopamine release in rat striatal tissues in vitro [161, 162], indicating an important role for $\alpha 6\beta 2^*$ nAChRs in this well-established effect of nicotine. Subsequently, the $\beta 3$ subunit was shown to be an integral component of these α -conotoxin MII-sensitive receptors [163, 164].

Synthesis of an [125 I] α -conotoxin MII analog allowed the distribution of $\alpha 6$ -nAChRs in brain to be mapped by autoradiography [127]. These mapping studies showed that the $\alpha 6$ receptors have a relatively narrow distribution in the brain. Their highest densities are in the retina and brain areas to which the visual tract projects, such as the superior colliculus and lateral geniculate nuclei [54, 56, 102, 127, 160]. Relatively high densities of $\alpha 6$ -nAChRs are also found in the striatum and nucleus accumbens [127, 160, 165]. In fact, $\alpha 6\beta 2^*$ nAChRs are found on the dopamine axon terminals of rats, mice, and primates [55, 161, 165–169], accounting for their involvement in nicotine-stimulated dopamine release measured in vitro. The $\alpha 6$ subunit appears capable of forming one or more mixed heteromeric receptors with $\alpha 4$, $\beta 2$ and $\beta 3$ subunits [55]; therefore, further studies are required to determine the complete subunit compositions of the nAChR subtypes involved in dopamine release, but one leading candidate would be the $\alpha 6\beta 2\beta^*$ subtype.

Other α -conotoxins appear to be specific for other nAChR subtypes. For example, α -conotoxin AuIB appears to be specific for $\alpha 3\beta 4^*$ nAChRs [170], and studies with it have helped to establish roles for these receptors in the rat medial habenula [146]. In

addition, nicotine-stimulated norepinephrine release in rat hippocampus synaptosomes has a different pharmacological profile compared to dopamine release in the striatum [171]. The agonist potencies and particularly the efficacy of cytisine suggested that the norepinephrine release was mediated by $\alpha 3\beta 4^*$ receptors [171]. This suggestion was supported by later studies with α -conotoxin AuIB in vitro [170], as well as by studies that showed that in vivo microinjection of α -conotoxin AuIB into the locus ceruleus, the cell body origin of the norepinephrine axons, partially blocked the release of norepinephrine [172]. Interestingly, these studies found that microinjected α -conotoxin MII also partially blocked norepinephrine release, suggesting that $\alpha 6\beta 2$ (or $\alpha 3\beta 2$) nAChRs are also involved, or possibly a mixed heteromeric subtype comprised of an α subunit in association with both $\beta 2$ and $\beta 4$ subunits [172].

Determining the subunit compositions of nAChRs involved in important functions is a critical step in delineating the pharmacology of those receptors. The studies of the $\alpha 6$ nAChRs involved in dopamine release illustrate how a multipronged approach utilizing selective ligands, subunit-selective antibodies, and knockout mice can be brought to bear on the question of which nAChR subtypes is involved in a specific function. Because nAChRs appear to mediate the release of several different neurotransmitters in brain pathways, they are implicated in diverse and important functions, such as the reward pathways associated with dopamine, arousal and motivation associated with norepinephrine, anxiolytic responses associated with GABA, and cognitive processes associated with acetylcholine and glutamate. In some cases there appears to be considerable redundancy built into these functions. For example, nicotine-stimulated dopamine release from striatal synaptosomes is mediated by at least two different nAChR subtypes (the leading candidates are $\alpha 6\beta 2\beta 3^*$ and $\alpha 4\beta 2^*$), both of which are located on axons of dopaminergic neurons [55, 164, 167]. But interestingly, dopamine release stimulated by systemic injections of nicotine in rats and mice in vivo appears to originate at somatodendritic nAChRs located on the midbrain dopamine neuron cell bodies [167, 173, 174]. Moreover, receptors containing the $\alpha 6$ subunit do not seem to be required for this effect of systemic nicotine [167]. The full range of the physiological roles of these different nAChRs in the dopamine pathway is not known, but this is a crucial question that bears on the potential of these receptors as targets for drug interventions in disorders as diverse as Parkinson's disease, schizophrenia, Tourette's disease, attention-deficit disorders, and, of course, nicotine addiction.

4.4.2.3 Distribution of Heteromeric nAChRs. In addition to delineating the pharmacological profiles of the nAChR subtypes, binding studies have uncovered useful tools for probing nAChRs in the CNS. For example, the total population of heteromeric nAChRs can be mapped in autoradiographic studies with [125 I]EB, which labels all subtypes with very high affinity (50–300 pM). Alternatively, because of its high affinity and selectivity, [125 I]5-iodo-A-85380 can be used to label only nAChRs that contain $\beta 2$ subunits [121, 175]. Figure 4.2 compares the autoradiographic images of [125 I]EB and [125 I]A-85380 binding to nAChRs in adjacent sagittal sections of rat brain. Note the similarity in the distribution of the binding sites, but also note that [125 I]EB prominently labels the pineal gland and the fasciculus retroflexus (Fig. 4.2a), whereas [125 I]A-85380 does not (Fig. 4.2b). The presence of the $\beta 4$ -containing receptors is emphasized in Figure 4.1c, in which the tissue sections

Figure 4.2 Autoradiographic images of nAChRs labeled by $[^{125}\text{I}]\text{epibatidine}$ and $[^{125}\text{I}]\text{A-85380}$. nAChRs labeled by $[^{125}\text{I}]\text{epibatidine}$ and $[^{125}\text{I}]\text{A-85380}$ in adjacent sagittal sections of rat brain are shown in (a) and (b) respectively. In (c), the differences between the binding sites labeled by these two radioligands are emphasized by labeling adjacent sections with $[^{125}\text{I}]\text{epibatidine}$ in the presence of unlabeled A-85380 to mask all binding sites containing $\beta 2$ subunits. Adapted from [121].

were incubated with $[^{125}\text{I}]\text{EB}$ in the presence of 5 nM unlabeled A-85380 to mask the nAChR binding sites that contain $\beta 2$ subunits.

4.5 REGULATION OF nAChRs

4.5.1 Desensitization and Inactivation of nAChRs

During exposure to agonists, neuronal nAChRs desensitize rapidly, becoming unresponsive for a period of time. This phenomenon, which closely resembles the desensitization of muscle nAChRs described by Katz and Thesleff [176], is seen in virtually all neuronal nAChRs that have been examined. In the desensitized state nAChRs have much higher affinity for agonists than they do in their resting (activatable) state, which accounts for why the affinities of agonists measured in binding studies are so much higher than their potencies measured in studies of receptor function would predict. Moreover, in the prolonged presence of agonists, more receptors are recruited into the desensitized state. Consistent with this, agonists

are more potent in desensitizing nAChRs than in activating them both in vitro [137, 140, 142, 177–181] and in vivo [182, 183].

The difference in the potencies of nicotine to desensitize versus activate nAChRs depends on the receptor subtype. For example, nicotine was ~ 50 times more potent in desensitizing than in activating $\alpha 3\beta 4$ receptors expressed in frog oocytes, whereas it was > 200 times more potent in desensitizing than activating the $\alpha 4\beta 2$ subtype [181]. In mammalian cells expressing nAChRs, nicotine was ~ 9 times more potent in desensitizing $\alpha 3\beta 4$ receptors than in activating them [140], and again this difference in potency was much greater at $\alpha 4\beta 2$ receptors [137, 142]. In vivo, nicotine is ~ 5 times more potent in desensitizing nicotine-induced prolactin release in the rat than in stimulating the response [183].

The rate of onset of desensitization by agonists is concentration dependent and also varies among receptor subtypes [184–186]. The rate of recovery from desensitization depends on the concentration of agonist and in some cases on the duration of exposure [140, 187, 188]. Just as important, the rate of recovery from desensitization also varies with subtype. For example, the $\alpha 3\beta 4$ subtype appears to recover faster than the $\alpha 4\beta 2$ subtype from nicotine-induced desensitization [181].

Desensitization of nAChRs by acetylcholine released by neurons in vivo, if it occurs at all, is brief because the agonist is rapidly hydrolyzed by cholinesterase. But following administration of nicotine or other agonists that are not rapidly degraded, desensitization lasts much longer, as the agonist continues to circulate, bind to receptors, and presumably recruit more of them into the desensitized state. For example, a single injection of nicotine, which has a plasma half-life of < 60 min in the rat [189], can produce profound desensitization of some CNS responses that lasts for several hours or longer [183, 190]. In fact, because of this prolonged desensitization, nicotine's predominant effect over time (i.e., its time-averaged effect), at least at some receptors, is that of an antagonist [142, 183, 187].

The degree to which a drug behaves as a time-averaged antagonist after a single acute administration depends on its affinity for a particular receptor subtype as well as its rate of removal from nearby cells, where it could be sequestered and then slowly released to maintain receptor desensitization [191]. Because nicotine and most other agonists have much higher affinity for $\alpha 4\beta 2^*$ than for $\alpha 3\beta 4^*$ nAChR subtypes, functions mediated by $\alpha 4\beta 2^*$ receptors, which are the predominant subtype in the CNS, are probably more affected by desensitization than are the $\alpha 3\beta 4^*$ receptors in the ganglia; moreover, nicotine concentrations in the brain typically exceed those in plasma [192, 193]. The result is that under conditions of repeated administration of nicotine at the doses taken in by a cigarette smoker, most of the $\alpha 4\beta 2^*$ receptors in the brain are probably desensitized nearly all of the time; the probable exception is after overnight abstinence from smoking (i.e., ~ 4 – 6 half-lives for plasma nicotine), when a significant fraction of receptors would be expected to recover function.

In addition to classical receptor desensitization, which reverses over a time frame of seconds to minutes after removal of the agonist, a more extended loss of receptor function may take place during prolonged or repeated exposure to nicotine or other agonists. This more durable desensitization, which is referred to as receptor *inactivation*, has been seen to varying degrees in nAChRs in electric tissue [194], rat PC12 cells [177, 195, 196], human SH-SY5Y cells [187], rodent brain tissues [178, 197], and rats in vivo [182]. Inactivation is also found in heterologously expressed receptors [140, 198–200], suggesting that it is an intrinsic property of the receptor,

like acute desensitization. In fact, it is even possible that rather than being a distinct condition or engaging different mechanisms, inactivation may simply be protracted desensitization resulting from slow escape of a sequestered agonist like nicotine from cells near the receptor [191]. In either case, $\alpha 3\beta 4$ receptors again recover function rather rapidly even from prolonged exposure to agonists. For example, after a five-day exposure to a high concentration of nicotine, $\alpha 3\beta 4$ receptors heterologously expressed in mammalian cells recover function with a half-time of 11 min [140]. The rapid recovery of $\alpha 3\beta 4$ receptor activity may explain why ganglionic functions can be maintained fairly well between the episodes of self-administration of nicotine that occurs over long periods of time in a smoker.

During the periods that $\alpha 4\beta 2^*$ receptors are desensitized, the $\alpha 3\beta 4^*$ receptors in brain, as well as any other receptor subtypes that desensitize less readily or recover more quickly, probably take on added functional significance. For example, during those periods that nicotine cannot stimulate dopamine release via the desensitized $\alpha 4\beta 2^*$ receptors, it might still be capable of stimulating norepinephrine release, which appears to be mediated by $\alpha 3\beta 4^*$ receptors [170, 171]. These factors could be particularly important to the mechanisms related to induction and/or maintenance of nicotine addiction as well as to the physiological and subjective effects elicited by withdrawal from nicotine.

4.5.2 Agonist-Induced Up-regulation of nAChRs

The density of nAChRs increases during chronic exposure to nicotine or other agonists. This unusual characteristic, referred to as receptor up-regulation, was first seen as an increase in nAChR binding sites in brains from rats and mice treated in vivo with nicotine for 10–14 days [201–203], but nicotine-induced up-regulation has since been found in cultured cells expressing virtually every nAChR subtype and subunit combination examined [123, 138, 140, 187, 204–206]. Moreover, as shown in Figure 4.3, nAChR binding sites are also increased in autopsied brains from people who smoked compared to the binding sites in brains from age-matched controls [207–209]. The clear implication is that the nicotine-induced increase in brain nAChRs may be linked to nicotine addiction.

Nicotine exposure increases nearly all nAChR subtypes expressed by cells in culture; in contrast, the nicotine-induced increase in nAChRs in vivo is much more limited. For example, chronic nicotine treatments that increase nAChRs in rat brain do not increase the receptors in any peripheral tissues examined, including superior cervical ganglia, adrenal gland, or pineal gland [210, 211]. The reasons for this difference in regulation between CNS and peripheral nAChRs during chronic exposure to nicotine are not yet completely known, but the receptors increased in brain by nicotine treatments are the $\alpha 4\beta 2^*$ subtype [106], whereas the nAChRs in the peripheral tissues are predominantly $\alpha 3\beta 4^*$ receptor subtypes. Thus, the higher affinity of nicotine for the $\alpha 4\beta 2^*$ receptors as well as the higher nicotine concentration reached in brain during chronic administration could both contribute to the difference in regulation. Furthermore, an extracellular domain of the $\beta 2$ subunit itself may be critical to the mechanisms that underlie the up-regulation [212].

Perhaps as intriguing as the differences in regulation between nAChR subtypes in brain and periphery is that the increase in $\alpha 4\beta 2^*$ receptors appears to vary across brain regions and even between neighboring brain nuclei [213–215]. This suggests

Figure 4.3 Autoradiographic images of nAChRs labeled by [^3H]epibatidine in human frontal cerebral cortex from a nonsmoker and a smoker. These images are representative of the increases in nAChRs that are found in brains from smokers. The lower figure depicts the very low level of nonspecific binding with [^3H]epibatidine. From [209].

that there are differences among the $\alpha 4\beta 2^*$ receptors that affect their susceptibility to up-regulation by nicotine. One possibility is that the presence of an additional subunit in a mixed heteromeric $\alpha 4\beta 2^*$ receptor affects the up-regulation. For example, $\sim 15\%$ of the $\alpha 4\beta 2^*$ receptors in rat cerebral cortex and $\sim 25\%$ of the receptors in hippocampus contain an $\alpha 5$ subunit, and the receptors that contain these subunits do not appear to be up-regulated by chronic nicotine [155]. Another possibility is that factors intrinsic to particular neurons (e.g., the rate of receptor turnover) affect the degree to which nicotine can up-regulate the receptors.

Interestingly, a recent study found that $\alpha 6$ -containing nAChRs, which had not been examined in earlier studies, were increased in several areas of brain, including the striatum, from rats that had been trained to chronically self-administer nicotine intravenously [216]. In contrast, in mice that had received nicotine chronically via continuous infusion or in their drinking water [168, 217] and in rats that received nicotine via osmotic mini-pumps [218], the $\alpha 6$ -containing receptors in the striatum were actually decreased. It is probable that technical differences in the receptor measurements or possibly differences between species or rat strains account for these

opposite results for the $\alpha 6$ receptors (but it would be particularly interesting if the method of nicotine administration—voluntary self-administration versus nonvoluntary infusions—influences its effects on receptors).

The nicotine-induced increase in nAChR binding sites in cells in culture is usually associated with increased receptor function [134, 138, 142, 206, 219]; however, there are also instances where the receptor binding sites are increased but function appears to be nearly absent [220]. In brain tissues from rats treated chronically with nicotine, some studies have found increased nAChR-mediated responses corresponding to the increased receptor binding sites [221–224], but other studies using brain tissues from rat or mouse found either no increase or even a decrease in nAChR-mediated responses [225–227]. To complicate this picture further, differential effects on nicotine-stimulated release of two or more neurotransmitters were found in brain tissues from the same chronically treated rats [222, 224]. Moreover, in a study designed to measure a CNS nAChR-mediated response in vivo, nicotine-stimulated prolactin release in rats was abolished for more than a week after chronic administration of nicotine [182].

Some of the impressive variability in the results of studies that have assessed function after chronic administration of nicotine in vivo might be explained by the fact that different nAChR subtypes are associated with the release of different neurotransmitters. For example, nicotine-stimulated norepinephrine release in the hippocampus is mediated at least in part by an $\alpha 3\beta 4^*$ subtype [170, 171], while nicotine-stimulated dopamine release from striatal synaptosomes appears to be mediated by an $\alpha 4\beta 2^*$ subtype, which is presumably increased by chronic administration of nicotine, as well as an $\alpha 6\beta 2^*$ subtype that appears to be decreased by chronic nicotine [168, 217, 218]. Moreover, the variability in the results of the functional status of nAChRs after chronic administration of nicotine probably also reflects an interplay between an increase in $\alpha 4\beta 2^*$ receptors and reversible desensitization that prevents their function. If that is the case, after chronic administration, there might be only a window in time when an increase in receptor function would be measurable. This window would correspond to the period when the receptors have recovered from desensitization but are still increased. Furthermore, it is possible that there are factors at work here, either technical (e.g., incomplete washout of nicotine from brain tissues in vitro) or pharmacokinetic (e.g., long-term sequestration of nicotine in brain), that in some cases might not have been fully accounted for in assessing functional responses after chronic administration of nicotine.

Despite their potential for function, the increased $\alpha 4\beta 2$ receptors in a smoker are probably desensitized most of the time. This leads to the interesting possibility that self-administration of nicotine may be impelled by the need to prevent the withdrawal state by keeping the receptors desensitized, thus preventing the increased activity that would occur if the up-regulated receptors were fully functional. This could set up an oscillation between overstimulation of critical brain circuits due to the increased receptors followed rapidly by underactivity of the same circuits due to receptor desensitization. If that happens, it is not hard to imagine how it could maintain the repetitive, self-reinforcing behavior we call addiction.

Although it is not known how an increase in brain receptors affects complex behaviors, nicotine-induced up-regulation of nAChRs is an unusual and intriguing phenomenon, and the cellular/molecular mechanisms underlying the increase in receptors are the focus of much research. The increase in brain $\alpha 4\beta 2$ nAChRs induced by nicotine does not depend on increased transcription of mRNA [204,

214, 228], which obviously places posttranscriptional events at the center of focus. The mechanisms that have been proposed to explain nicotine-induced upregulation of $\alpha 4\beta 2$ nAChRs are derived from studies of receptors heterologously expressed in mammalian cells. These mechanisms include (1) slower removal and degradation of cell surface receptors [134, 204, 229], (2) increased assembly of receptors [134, 142, 212, 228, 230, 231], (3) increased insertion of receptors onto the cell surface [232], and (4) altered conformation of cell surface receptors that results in their stabilization in a state with high affinity for and sensitivity to agonists [229, 233].

Each of these mechanisms could theoretically explain the observations of increased binding and function of receptors during exposure to nicotine, but the most compelling data so far, derived from $\alpha 4\beta 2$ receptors heterologously expressed in mammalian cells, point to a combination of effects of nicotine. The first effect is increased maturation and final assembly of receptor pentamers in the endoplasmic reticulum. According to this hypothesis, nicotine (and other agonists) can bind to an immature $\alpha 4\beta 2$ subunit oligomer, perhaps a tetramer, and act as a chaperone to promote the introduction of the third $\beta 2$ subunit into the receptor, following which the pentamer undergoes final processing and transport to the cell surface as a mature, functional receptor¹ [142, 231]. The promotion of receptor assembly by nicotine is at least in part dependent on a “microdomain” in the $\beta 2$ subunit near the interface with the α subunit [212], which might account for the observation that in vivo $\alpha 4\beta 2$ but not $\alpha 3\beta 4$ receptors are increased.

In addition to promoting increased assembly of $\alpha 4\beta 2$ nAChRs, nicotinic agonists appear to slow their removal from the cell surface and their degradation [142, 204]. The mechanism that results in stabilization of $\alpha 4\beta 2$ receptors is probably no less important than increased assembly, but it is not yet known. It is possible, however, that the fully assembled receptors on the cell surface are less tempting or accessible targets for degradative enzymes. On the other hand, if nicotine affects receptor assembly and stability independently, it could explain why $\beta 4$ -containing receptors expressed in cultured cells are increased by nicotine, but not to the same extent as $\beta 2$ -containing receptors [123].

4.6 CONCLUSIONS

As nAChRs enter the second century since their discovery, we know a great deal about their subunit structure, channel function, and regulation. Their crucial physiological role in the autonomic nervous system is well established and their many potential roles in the CNS are becoming clearer. In the limited number of autonomic and sensory ganglia that have been examined, $\alpha 3\beta 4^*$ receptors predominate. In the CNS, although there are potentially a large number of receptor subtypes based on possible subunit combinations, a relatively small number of subtypes seems to be highly represented

¹Since the site of action of nicotine to increase assembly of receptors is intracellular, this mechanism indicates that even charged quaternary amine nicotinic agonists, like carbamylcholine, which would not be expected to readily cross the cell membrane to reach the endoplasmic reticulum to promote increased assembly, probably do get internalized in cells, albeit slowly, over the course of the several hours to days of incubation [142, 231].

in most regions. These include the homomeric $\alpha 7$ receptor and several heteromeric receptors comprising the $\alpha 4\beta 2^*$ and to a lesser extent $\alpha 3\beta 4^*$ subtypes. Although all nAChRs, but especially the heteromeric subtypes, share many pharmacological characteristics, some ligands and drugs have emerged that can distinguish among the subtypes, especially between those containing $\beta 2$ versus $\beta 4$ subunits. The likely crucial involvement of nAChRs in nicotine addiction makes them an important target for intervention in this disorder. Furthermore, because nAChRs in the CNS seem to be strategically located to modulate the release of several important neurotransmitters, including dopamine, norepinephrine, acetylcholine, GABA, and glutamate, they may influence a wide range of CNS functions and pathways. Consequently, drugs aimed at nAChR subtypes have great therapeutic potential in conditions as diverse as cognitive disorders, attention-deficit disorders, schizophrenia, Tourette's syndrome, Parkinson's disease, and neuropathic pain. It is therefore very likely that the pharmacology of these receptors will continue to be of great interest well into the next 100 years.

5.1 INTRODUCTION

Acetylcholine (ACh) is one of the major neurotransmitters in both the central and peripheral nervous systems. Historically, the effects of ACh that are mimicked by the alkaloid muscarine and that are selectively blocked by atropine are referred to as muscarinic effects. Molecular cloning studies have shown that the muscarinic effects of ACh are mediated by a family of cell surface receptors referred to as muscarinic ACh receptors (M₁–M₅ mAChRs; [1–3]).

mAChRs modulate the activity of many fundamental central and peripheral functions. In the central nervous system (CNS), mAChRs play important roles in most cognitive functions and many key motor, autonomous, sensory, and behavioral processes [4–6]. Importantly, disturbances in the central muscarinic cholinergic system have been implicated in several pathophysiological conditions, including Alzheimer's and Parkinson's disease, depression, epilepsy, and schizophrenia [7, 8].

In the body periphery, mAChRs mediate the well-known functions of ACh at parasympathetically innervated effector organs, including slowing of the heart, contraction of smooth muscle, and stimulation of glandular secretion [4, 9].

5.2 DISTRIBUTION OF mAChRs

The individual mAChRs are widely expressed in nearly all parts of the CNS and the body periphery [10–12]. Characteristically, each tissue or organ expresses multiple mAChR subtypes, with only very few exceptions (the heart almost exclusively expresses M_2 receptors). Detailed immunocytochemical studies in rat hippocampus [13] and striatum [14] have shown, for example, that multiple mAChR subtypes are expressed on specific neuronal populations both pre- and postsynaptically. It is likely that similarly complex expression patterns are present in most other regions of the brain and in many peripheral tissues.

The distribution patterns of the M_1 – M_5 mAChRs have been described in several excellent reviews ([10–12, 15]; see also Table 5.1). In brief, M_1 mAChRs are present at particularly high levels in the forebrain, including cerebral cortex, hippocampus, and striatum. M_2 receptors are widely expressed both in the CNS and in the body periphery, particularly in the heart and in smooth muscle tissues. Like the M_2 receptor, the M_3 mAChR subtype is widely expressed in different regions of the brain and in peripheral organs, including smooth muscle and glandular tissues. M_4 receptors are preferentially found in the CNS, particularly in different areas of the forebrain. M_5 receptors are expressed, at rather low levels, in both neuronal and nonneuronal cells [15]. Interestingly, M_5 receptor messenger ribonucleic acid (mRNA) represents the only mAChR mRNA that can be detected in dopaminergic neurons of the midbrain [19, 20].

5.3 GENERAL STRUCTURAL FEATURES OF mAChRs

The M_1 – M_5 mAChRs are prototypical members of the superfamily of class I G-protein-coupled receptors (GPCRs; [1–3]). Class I GPCRs, which are also referred to as rhodopsinlike receptors, share about 20 highly conserved amino acids (underlined in Fig. 5.1). The structural hallmark of mAChRs and all other GPCRs is the presence of seven α -helically arranged transmembrane domains (TMs I–VII; Fig. 5.1) which form a tightly packed transmembrane core. The N-terminal portion of the receptor protein is located extracellularly, whereas the C-terminal segment protrudes into the cytoplasm. The seven transmembrane helices are linked by three intracellular (i1–i3; Fig. 5.1) and three extracellular loops (o2–o4; Fig. 5.1).

At present, bovine rhodopsin, in its inactive state, is the only GPCR for which high-resolution structural information is available [24]. Molecular modeling studies suggest that the M_1 – M_5 mAChRs share a high degree of structural similarity with that of the rhodopsin template, especially within the regions endowed with secondary structure [25, 26]. A characteristic structural feature of the mAChRs is the presence of a rather large i3 loop (157–240 amino acids in length), which, except for the N- and C-terminal segments, displays virtually no sequence homology among the different subtypes. The N- and C-terminal portions of the i3 loop play important roles in

TABLE 5.1 mAChR Family: Pharmacological and Functional Properties and Anatomical Distribution by mAChR Subtype

Property	M ₁	M ₂	M ₃	M ₄	M ₅
Number of aminoacids (human)	460	466	590	479	532

^aFrom [15a].

^bExcept for certain snake toxins, such as MT3 or MT7, the degree of subtype preference of so-called subtype-selective muscarinic antagonists is usually relatively small (for a summary of affinity values, see [3]).

^cMT3 and MT7 are toxins isolated from the venom of the green mamba (*Dendroaspis augusticeps*) [16, 17].

^dM₅ mAChRs are pharmacologically distinct in that they display very low affinity for antagonists such as AF-DX 116 and its derivatives [3, 18].

^eNote that mAChRs are present in nearly all cell types, tissues, and/or organs. Summarized here are the mAChR expression patterns for some key tissues or organs. The symbols + +, +, and (+) indicate relative mAChR protein and/or mRNA expression levels. However, relative mAChR expression levels may differ among species.

receptor – G protein coupling [2, 22], whereas the central portions of the i3 loop are involved in the regulation of receptor activity (see below). The five receptor subtypes share the highest degree of sequence homology with the seven membrane-spanning domains which are known to be involved in ACh binding [2, 25]. The three-dimensional organization of the mAChR proteins and the potential functional roles of several conserved structural features such as a disulfide bond connecting the top of TM III with the o3 domain, the attachment of sugar chains at N-terminal Asn residues, and the palmitoylation of Cys residues present in the C-terminal tail have been reviewed in detail previously [2].

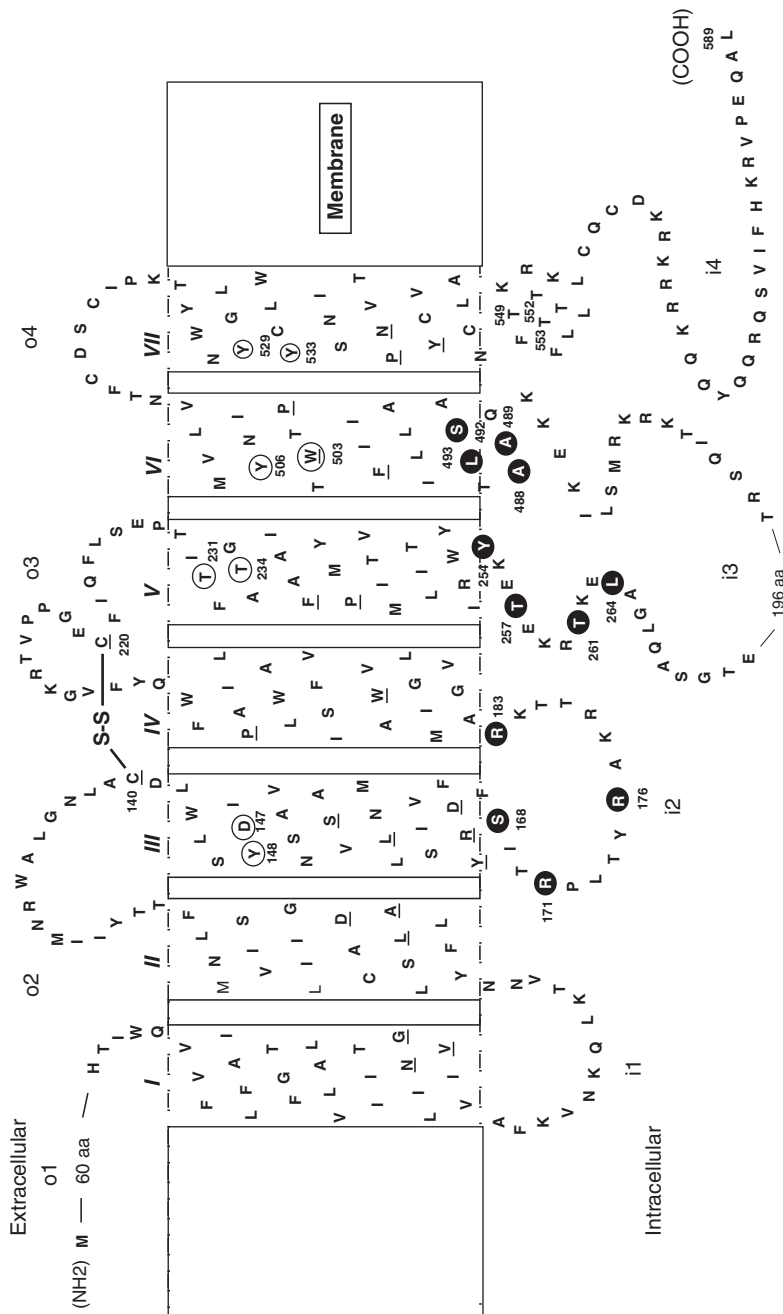

Figure 5.1 Predicted transmembrane topology of rat M_3 mAChR showing functionally important residues. Like all other GPCRs, the M_3 mAChR consists of an extracellular N-terminal domain (o1), seven transmembrane domains (TMs I–VII) connected by three extracellular (o2–o4) and three intracellular (i3) loops, and an intracellular C-terminal tail (i4). Amino acids which are highly conserved among class I GPCRs are underlined. Many of these amino acids play key roles in the agonist-induced conformational activation of the receptor protein [2, 21, 22]. Residues highlighted by open circles are predicted to be involved in the binding of ACh and other classical muscarinic agonists [2]. The amino acids highlighted by filled circles have been shown to determine the ability of the M_3 mAChR to selectively interact with G proteins of the $G_{q/11}$ family [2, 21, 22]. Only the membrane-proximal portions of the o1 and i3 domains are shown. Numbers indicate amino acid positions within the rat M_3 mAChR sequence [23].

5.4 MUSCARINIC LIGANDS AND MECHANISMS INVOLVED IN LIGAND BINDING

5.4.1 Agonists

Site-directed mutagenesis, biochemical, and molecular modeling studies indicate that ACh binds to the M₁–M₅ receptors within a cleft enclosed by the ringlike arrangement of TMs I–VII about 10–15 Å away from the membrane surface [2, 25]. The amino acids involved in ACh binding are located on different TM helices, primarily on TMs III, V, VI, and VII ([2, 25]; Fig. 5.1). Importantly, the positively charged ammonium head group of ACh (or the amino/ammonium head group of other classical muscarinic agonists or antagonists) is engaged in an ion–ion interaction with a TM III aspartate residue (D147 in Fig. 5.1) which is conserved among all biogenic amine GPCRs. This ion pair is surrounded by a cluster of aromatic amino acids located on TMs III, VI, and VII, thus creating a charge-stabilized aromatic cage [2, 25]. The specificity of ACh–mAChR binding depends on specific interactions of the ACh side chain with mAChR-specific amino acids facing the central ligand binding pocket. The molecular identity of these amino acids and their proposed interactions with the ACh molecule or related muscarinic agonists have been the subject of several recent reviews ([2, 25, 27]; also see Fig. 5.1).

Since the amino acids lining the ACh binding cavity are highly conserved among the M₁–M₅ mAChRs, the development of agonists or antagonists endowed with a high degree of mAChR subtype selectivity has proven to be a very difficult task. At present, agonists targeted at the classical ACh binding site that preferentially bind to a particular mAChR subtype are not available [3].

Several muscarinic agonists have been identified that display functional selectivity for a specific mAChR subtype, such as the M₁ mAChR, at least under certain experimental conditions. In almost all cases, these compounds are partial agonists, such as McN-A-343 (4-[[N-(3-chlorophenyl)carbamoyl]oxy]-2-butyryl]trimethylammonium chloride) and its derivatives [28], which usually show similar affinities for the different mAChR subtypes but preferentially activate one or more specific mAChRs, at least under certain experimental conditions, reflecting differences in efficacy. However, since the activity pattern of partial agonists greatly depends on receptor density, cell type, and actual response studied, it is difficult to predict what kind of functional activity/selectivity these agents will display *in vivo*.

5.4.2 Antagonists

The binding pocket of classical muscarinic antagonists, including atropine, scopolamine, or quinuclidinyl benzilate, partially overlaps with that of ACh and classical muscarinic agonists. However, antagonists usually form additional strong interactions with hydrophobic receptor residues, thus stabilizing the inactive state of the receptor [2, 25].

In general, the degree of selectivity of so-called mAChR subtype-selective muscarinic antagonists which are currently used to distinguish between different mAChR subtypes is rather limited [3]. Such compounds include, for example, pirenzepine (M₁ receptor preferring), triptamine and SCH 57790 (4-Cyclohexyl- α -[4[[4-methoxyphenyl]sulphonyl]-phenyl]-1-piperazineacetonitrile; M₂ receptor preferring), darifenacin (M₃ receptor preferring), or PD 102807 (3,6a,11,14-Tetrahydro-9-methoxy-2-methyl-12H-isoquino[1,2-b]pyrrolo[3,2-f][1,3]benzoxazine-1-carboxylic acid ethyl

ester M_4 receptor preferring) (Table 5.1). Antagonists that preferentially bind to M_5 receptors are not available at present.

As a general rule, multiple subtype-preferring muscarinic antagonists need to be applied to define the mAChR(s) mediating a specific physiological function. This approach has been highly useful to define the physiological functions of distinct mAChRs in *in vitro* studies [3]. In contrast, the use of this strategy in *in vivo* studies has frequently led to conflicting results, probably due the fact that antagonist potency *in vivo* does not only depend on actual receptor affinities but also on other, less well predictable factors such as drug distribution and metabolism.

Interestingly, several snake toxins have been identified that display an unprecedented degree of mAChR subtype selectivity [16, 17]. For example, MT7 (m1-toxin 1) and MT3 (m4-toxin) are highly selective antagonists for M_1 and M_4 mAChRs, respectively [16, 17]. The binding of these polypeptide ligands appears to involve interactions with less well conserved amino acids present on the extracellular surface of the receptors [17].

5.4.3 Allosteric Ligands

The binding of muscarinic ligands to the classical (“orthosteric”) binding site can be modulated by so-called allosteric ligands which interact with a secondary (allosteric) site [29, 30]. In fact, the mAChRs are generally used as a model system to illustrate the molecular mechanisms by which GPCR activity can be modulated by allosteric drugs [30]. The first allosteric muscarinic ligands to be identified were gallamine and other neuromuscular blocking drugs, including alcuronium and pancuronium. However, during the past decade, many structurally diverse ligands have been identified that appear to bind to sites different from the classical mAChR binding site [29, 30].

All mAChR subtypes have been shown to be susceptible to allosteric modulation. However, the molecular nature of this modulation differs among the individual receptor subtypes and depends on the choice of orthosteric and allosteric ligands and their concentrations. The receptor binding site for allosteric muscarinic ligands is thought to be located just “above” the classical ligand binding pocket involving residues located in the extracellular loops and the outermost segments of different TM helices. The existence of an allosteric site on the mAChRs may lead to novel therapeutic strategies aimed at “turning off” or “tuning up” signaling through distinct mAChRs subtypes [29–31]. Most allosteric muscarinic ligands retard the dissociation of muscarinic radioligands bound to the orthosteric site [30]. Some allosteric ligands have been shown to display positive cooperativity with ACh or certain muscarinic antagonists at specific mAChR subtypes. The thiamine metabolite, thiochrome, for example, is an allosteric enhancer at M_4 receptors but has no effect on ACh binding to the remaining four mAChR subtypes [32].

Tränkle et al. [33] were able to develop dimethyl-W84 (N,N'-bis[3-(1,3-dihydro-1,3-dioxo-4-methyl-2H-isoindol-2-yl)propyl]-N,N,N',N'-tetramethyl-1, 6-hexanediaminium diiodide) as the first allosteric muscarinic radioligand that can label an allosteric site on the M_2 mAChR. Interestingly, recent evidence suggests the existence of at least two allosteric sites with very different pharmacologies [34, 35].

Recent studies have also led to the identification of atypical muscarinic agonists that can activate M_1 receptors with rather high selectivity, most likely via interaction with an allosteric site. These agents include, for example, AC-42

[4-*n*-Butyl-1-[4-(2-methylphenyl)-4-oxo-1-butyl]-piperidine hydrogen chloride; [36] and *N*-desmethylozapine [37]. The development of subtype-selective allosteric muscarinic ligands for therapeutic purposes, particularly allosteric enhancers, therefore appears a very attractive goal.

5.4.4 Muscarinic Drugs in Current Clinical Use

Muscarinic agonists and antagonists are in clinical use for the treatment of various pathophysiological conditions [4, 38]. Muscarinic agonists such as pilocarpine and aceclidine are applied locally to the eye for the treatment of glaucoma to reduce intraocular pressure. Moreover, muscarinic agonists such as carbachol or bethanechol are employed in certain cases of atonia of the stomach, bowel, or urinary bladder. The muscarinic agonists pilocarpine and cevimeline are used to stimulate salivary secretion under conditions where the function of the salivary glands is impaired [39]. Scopolamine, a muscarinic antagonist, is highly effective in preventing motion sickness. Centrally acting muscarinic antagonists (e.g., trihexyphenidyl, procyclidine, or biperiden) are useful for the treatment of Parkinson's disease or Parkinson-like symptoms caused by the administration of antipsychotic drugs, probably due to their ability to reduce excessive striatal muscarinic neurotransmission resulting from the lack of striatal dopamine. Muscarinic antagonists are also widely used in the treatment of disorders characterized by an increased tone or motility of the gastrointestinal and urogenital tracts and in the local therapy of obstructive pulmonary diseases, including chronic bronchitis and bronchial asthma. Additional uses of muscarinic antagonists are in ophthalmology to produce mydriasis and/or cycloplegia, the treatment of peptic ulcer disease (e.g., pirenzepine) and certain forms of cardiac arrhythmias, and their application as part of routine preoperative medication, primarily to reduce reflex bradycardia and excessive bronchial secretion [4, 38].

5.4.5 Muscarinic Drugs: Potential Future Clinical Applications

A major problem associated with the clinical use of classical muscarinic drugs is the rather common occurrence of side effects, primarily due to the limited receptor subtype selectivity of the muscarinic drugs used and the widespread distribution of the individual mAChRs. It is likely that the development of muscarinic agonists and antagonists that can interact with individual mAChRs with a high degree of selectivity will lead to novel muscarinic drugs with reduced side effects and increased efficacy [7, 8]. For example, centrally acting selective M₁ receptor agonists may become useful in the treatment of Alzheimer's disease, and selective M₃ receptor antagonists are predicted to produce fewer side effects in the treatment of smooth muscle disorders, including urinary urge incontinence, irritable bowel syndrome, and chronic obstructive pulmonary disease [7, 8]. The application of subtype-selective muscarinic drugs may also be beneficial in the management of pain and in the treatment of schizophrenia [7, 8]. Recent studies with mAChR knockout (KO) mice have led to novel insights into the physiological and pathophysiological roles of the individual mAChR subtypes [40]. As a result, these studies have opened new avenues for the development of novel muscarinic drugs potentially useful in the treatment of a variety of pathophysiological conditions (see Section 5.14).

5.5 MECHANISMS INVOLVED IN mAChR ACTIVATION

The current view is that the inactive state of mAChRs and other GPCRs is maintained by specific interhelical interactions. Agonist binding to GPCRs is predicted to disrupt this interhelical network of interactions, replacing it with a new set of intramolecular contacts that stabilize the active receptor conformation(s). Site-directed mutagenesis studies with the M₁ mAChR have shown that the removal of several of the aromatic residues predicted to be in close proximity to the ACh ammonium head group leads to mutant receptors with greatly reduced G-protein coupling efficiencies [25, 27]. These findings are consistent with the concept that ACh binding leads to a tightening of the charge-stabilized aromatic cage around the ion pair formed by the quaternary head group of ACh and the conserved TM III Asp residue [25, 27].

The molecular nature of the ACh-induced conformational changes is not well understood at present. In any case, the conformational changes predicted to occur close to the ligand binding pocket need to be transmitted to the intracellular surface of the mAChR protein, enabling the receptor to productively interact with specific classes of heterotrimeric G proteins. Recent *in situ* disulfide crosslinking studies have shown, for example, that agonist activation of the M₃ mAChR leads to pronounced structural changes on the intracellular surface of the receptor protein [26, 41]. Receptor activation is predicted to be associated with conformational changes that increase the proximity of the cytoplasmic ends of TM VI and TM V [41] and of TM VII and TM I [26], respectively. These movements also appear to include major rotational movements of the cytoplasmic ends of TMs VI and VII [26, 41]. These agonist-induced structural changes are predicted to expose previously inaccessible residues or surfaces, for example on TMs III, VI, and VII, to G-protein heterotrimers, ultimately triggering productive receptor–G protein coupling.

During the past decade, several point mutations located in different receptor domains have been identified that render specific mAChR subtypes constitutively active [42–46], a phenomenon that has been observed with many other classes of GPCRs. It is generally assumed that the majority of these mutations interfere with the proper packing of the TM receptor core, thus mimicking, at least partially, the agonist-induced “opening” of the intracellular receptor surface. It should also be noted that constitutive receptor activity (activity in the absence of agonists) has also been observed with mAChRs expressed in native tissues, including cardiac membranes [47]. All classical muscarinic antagonists that have been tested so far are able to act as inverse agonists, being able to suppress constitutive signaling by wild-type (WT) or mutant mAChRs [47, 48].

Interestingly, a recent study analyzing mAChR–G protein interactions by the use of [³⁵S]-GTPγS (Guanosine-5'-O-(3-[³⁵S]-thio)-triphosphate) binding assays suggests that the specific G-protein coupling profile of a given mAChR may also depend on the chemical nature of the activating ligand [49]. This finding is consistent with observations made with many other classes of GPCRs, suggesting that structurally different agonists may stabilize slightly different active receptor conformations [50].

5.6 G-PROTEIN COUPLING PROPERTIES OF mAChRs

Based on their G-protein coupling properties, the M₁–M₅ mAChRs can be subdivided into two major functional subclasses [2, 3, 51]. The M₁, M₃, and M₅

mAChRs are preferentially coupled to G proteins of the $G_{q/11}$ family, which mediate the activation of different isoforms of phospholipase C β (PLC β), resulting in the breakdown of phosphatidyl inositol (PI) and the generation of the second messengers diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP $_3$). DAG activates protein kinase C (PKC), and IP $_3$ induces the release of calcium from intracellular stores. The resulting increase in intracellular calcium levels ($[Ca^{2+}]_i$) regulates the activity of many ion channels and enzymes including the activation of calmodulin-dependent protein kinases, adenylyl cyclases, and phosphodiesterases. The activated $G_{q/11}$ subunits can stimulate the activity of all members of the PLC β family (PLC β 1–4 [52]).

In contrast, the M_2 and M_4 mAChRs are selectively linked to G proteins of the $G_{i/o}$ class (these G proteins can be inactivated by treatment with pertussis toxin), which, at a biochemical level, inhibit the accumulation of intracellular cyclic adenosine monophosphate (cAMP) via inhibition of adenylyl cyclase [2, 3, 51]. Activation of the M_2 and M_4 mAChRs can also lead to the activation of the PLC β 2 and PLC β 3 isoforms [52, 53]. This response has been shown to be mediated by free $G\beta\gamma$ subunits released after activation of G proteins of the $G_{i/o}$ family [52, 53].

It should be noted, however, that the G-protein coupling preference of the individual mAChR subtypes is relative rather than absolute and depends on a number of factors including receptor and G-protein levels and cell type under investigation [2, 51].

The regulation of adenylyl cyclase activity by different mAChRs is particularly complex [51, 54]. One major complicating factor is the existence of at least nine adenylyl cyclase isoforms which differ in their regulation by different G-protein subunits and second messengers [55]. Activated $G_{\alpha_{i/o}}$ subunits generated by activation of M_2 and M_4 mAChRs can directly inhibit several adenylyl cyclase isoforms [55]. However, in certain cells or tissues, activation of G_q -coupled mAChRs may also result in reduced intracellular cAMP levels [51]. This response may involve the stimulation of a calcium–calmodulin sensitive phosphodiesterase activated by mAChR-mediated increases in $[Ca^{2+}]_i$ [56]. Moreover, when expressed at high levels in certain cell types, both G_q - and G_i -linked mAChRs can also couple to G_s to stimulate adenylyl cyclase activity [51, 54]. G_q -coupled mAChRs have also been shown to increase intracellular cAMP levels via activation of calcium–calmodulin-sensitive adenylyl cyclases [57]. Moreover, Olanas et al. [58] demonstrated that G_i -coupled mAChRs expressed in the rat olfactory bulb can facilitate increases in intracellular cAMP levels via $G\beta\gamma$ -dependent activation of adenylyl cyclases II and IV.

Accumulating evidence also suggests that the G-protein coupling profiles of the individual members of the two functional classes of mAChRs may not be identical [2, 22, 51]. Migeon et al. [59], for example, demonstrated that the M_2 and M_4 mAChRs, when transiently expressed in JEG-3 cells, couple to inhibition of adenylyl cyclase by overlapping but different G-protein $\alpha_{i/o}$ subunits. Similarly, studies with stably transfected CHO cell lines showed that the M_1 receptor coupled to stimulation of adenylyl cyclase with significantly greater efficiency than the M_3 receptor subtype [60].

The selectivity of mAChR–G protein interactions can also be modulated by the type of G-protein $\beta\gamma$ complexes expressed within a cell [61], providing an additional layer of functional complexity. Studies with antisense oligonucleotides demonstrated,

for example, that specific $G\beta$ ($\beta 3$) and $G\gamma$ ($\gamma 4$) subunits are required to allow M_4 receptor-mediated inhibition of voltage-sensitive calcium channels in GH3 cells via coupling to $G\alpha_{o1}$ [61]. Similarly, studies with M_2 mAChR-expressing Sf9 insect cells showed that the M_2 receptor could activate G_o heterotrimers with different efficacies, depending on the molecular identity of the β and/or γ subunit contained within the G-protein heterotrimer [62, 63].

5.7 STRUCTURAL BASIS OF SELECTIVITY OF mAChR-G PROTEIN INTERACTIONS

Following agonist binding, mAChRs, like other GPCRs, undergo conformational changes that allow residues located on the intracellular receptor surface to productively interact with heterotrimeric G proteins. Studies with chimeric mAChRs, complemented by site-directed mutagenesis studies, have identified the key receptor domains and amino acids that determine the G-protein coupling profile of the individual mAChRs. This work has been reviewed in detail previously [2, 22]. The mAChR regions known to be critically involved in determining the selectivity of receptor-G protein interactions are the i2 domain and the membrane-proximal portions of the i3 loop. Several studies have shown that these regions act in a cooperative fashion to determine which set of G proteins are activated by a specific mAChR [2, 22]. Fig 5.1 highlights the specific residues in the rat M_3 muscarinic receptor that are critically involved in the selective coupling of this receptor subtype to G proteins of the G_q family. We previously proposed that the functionally important residues at the N- and the C-terminus of the i3 loop form two adjacent hydrophobic patches that project into the interior of the receptor protein [2, 21, 22]. These two hydrophobic surfaces, together with several hydrophilic residues in the i2 loop, are thought to form a G-protein binding pocket, representing the primary structural determinant of the selectivity of mAChR-G protein interactions. According to this model, this functionally critical receptor surface cannot be properly recognized by the G protein in the resting state of the receptor. However, the agonist-induced conformational changes are thought to lead to an opening of the intracellular receptor surface, thus allowing the G protein to make productive contacts with key residues on the receptor protein ([2, 21, 22]; see Section 5.5 for more details).

The molecular architecture of the receptor-G protein complex still remains only poorly defined. Many studies have shown that the C-terminus of the G-protein α subunits plays a key role in determining the selectivity of receptor-G protein interactions [64–66]. To identify the site on the M_2 mAChR that can interact with the C-terminus of $\alpha_{i/o}$ subunits, Liu et al. [65] took advantage of the observation that the M_2 mAChR did not recognize wild-type α_q but was able to efficiently couple to mutant α_q subunits in which the last five amino acids of α_q were replaced with the corresponding α_i or α_o sequences. The outcome of a series of loss- and gain-of-function mutagenesis studies strongly suggested that a four-amino-acid motif ('VTIL', corresponding to Val385, Thr386, Ile389, and Leu390 in the human M_2 mAChR), located at the i3 loop-TM VI junction, can selectively recognize the C-terminus of $\alpha_{i/o}$ subunits [65]. This agonist-induced interaction is predicted to play a key role in productive receptor-G protein coupling.

To identify the amino acids on the rat M_3 mAChR that can interact with the C-terminus of α_q , Kostenis et al. [66] again used a coexpression strategy involving the use of M_2/M_3 hybrid mAChRs and chimeric G-protein α subunits. This analysis showed that the AALS motif (Ala488, Ala489, Leu492, and Ser493 in the rat M_3 mAChR sequence; Fig. 5.1), which corresponds to the VTIL sequence in the M_2 mAChR, plays an important role in recognizing the C-terminal amino acids of α_q . However, these studies also suggested that amino acids within the i2 loop and the N-terminal portion of the i3 domain of the M_3 mAChR may also be able to contact the C-terminus of α_q . One possible explanation for this observation is that the C-terminal portion of α_q can contact a receptor surface composed of amino acids located on different intracellular receptor regions. This notion is also supported by loss-of-function studies [67] examining the ability of a C-terminal α_t (transducin) peptide to bind to WT and mutant versions of rhodopsin.

Although it is clear that the C-terminus as well as other regions of the G-protein α subunits play a predominant functional role in receptor–G protein coupling, considerable evidence suggests that G-protein $\beta\gamma$ complexes can also modulate the selectivity of receptor–G protein interactions, presumably by directly contacting the receptor protein [61, 68].

5.8 MODULATION OF mAChR–G PROTEIN COUPLING BY RGS PROTEINS

The efficiency of mAChR–G protein interactions is modulated by the activity of a class of proteins referred to regulators of G-protein signaling (RGS proteins [69]). RGS proteins act as negative regulators of G-protein signaling by serving as GTPase-activating proteins for $G\alpha$ subunits, thereby accelerating G-protein inactivation [69]. Several recent studies have shown that signaling through distinct mAChR subtypes is reduced by the activity of specific classes of RGS proteins (see, e.g., [70–75]). Interestingly, Bernstein et al. [71] recently reported that RGS2 can bind simultaneously to the i3 loop of the M_1 mAChR and activated $G\alpha_q$. Moreover, the ability of RGS2 to inhibit M_1 receptor-mediated activation of $PLC\beta$ correlated well with its ability to bind to the i3 loop of the M_1 receptor. These data support the novel concept that the specificity of RGS–G protein interactions *in vivo* is modulated by selective recognition of specific members of the RGS family by a given GPCR.

5.9 SIGNALING PATHWAYS MODULATED BY mAChR ACTIVATION

As already noted in Section 5.6, mAChRs regulate, either directly or indirectly, the activity of a very large number of intracellular signaling pathways and molecules. These include, besides the pathways already discussed earlier in this chapter, phospholipases A_2 and D, small G proteins of the rac and rho family, protein tyrosine kinases such as Bruton's tyrosine kinase [76] and PYK2 (Proline-rich tyrosine kinase 2; [77]), and different NO synthase isoforms [54, 78]. A detailed description of these pathways is beyond the scope of this chapter (for a recent review, see [78]). The following section will summarize a series of studies dealing with the role of mAChRs

in regulating different mitogen-activated protein kinase (MAPK) pathways. These kinases play key roles in many important physiological functions, including, for example, regulation of gene transcription, cellular growth and differentiation, and synaptic plasticity [78].

5.10 MODULATION OF MAPK PATHWAYS

A wealth of evidence indicates that agonist stimulation of mAChRs, as well as of many other GPCRs, can activate various MAPKs [51, 78, 79]. mAChR-mediated activation of MAPK can occur via a variety of cellular mechanisms, depending on the type of mAChR and cell studied. MAPK activation can be mediated by both activated $G\alpha$ subunits and $G\beta\gamma$ complexes [51, 78, 79].

The MAPK family consists of four major subgroups, the extracellular signal-regulated kinases (ERK1 and 2), the stress-activated protein kinases or c-Jun N-terminal kinases (SAPKs/JNKs), p38 kinases, and ERK5 [79].

ERK1 (p44 MAPK) and ERK2 (p42 MAPK) can be activated by stimulation of either of the five mAChR subtypes [78, 80]. Depending on the investigated cell type and the specific experimental conditions used, M_1 , M_3 , and/or M_5 mAChR-mediated ERK activation can occur via PKC-dependent and PKC-independent mechanisms [78]. M_2 and M_4 mAChR-mediated ERK activation has been shown to be mediated by free $G\beta\gamma$ complexes. Lopez-Ilasaca et al. [81], for example, demonstrated that stimulation of M_2 mAChRs transiently expressed in COS-7 cells leads to $G\beta\gamma$ -dependent activation of phosphoinositide 3-kinase γ (PI3K γ), which in turn triggers the activation of the Shc–Grb2–Sos–Ras pathway, resulting in increased MAPK activity. However, another study showed that MAPK stimulation can also be mediated by activated $G\alpha_i$, generated by stimulation of M_2 receptors expressed by HEK-293T cells [82]. Additional studies suggested that MAPK stimulation is mediated by a $G\alpha_i$ -dependent reduction in the levels of the active form of Rap1, an inhibitor of Ras function, involving the activation of a novel Rap1 GTPase-activating protein [82].

Several studies have shown that activation of various mAChR subtypes can also lead to the activation of JNK, p38 kinases, and ERK5 in different cell types or tissues. As is the case for mAChR-dependent activation of ERK1 and 2, multiple cellular pathways appear to participate in mAChR-mediated stimulation of these MAPKs [78, 79].

Activation of several GPCRs, including the M_1 mAChR, can also lead to the transactivation of cell surface growth factor receptors known to be linked to MAPK activation. For example, studies with transfected Rat-1 and COS-7 cells demonstrated that M_1 mAChR activation leads to the transactivation of the EGF (epidermal growth factor) receptor [83]. This transactivation process appears to require the activity of a metalloproteinase which releases an EGF-like factor capable of activating the EGF receptor [83]. In contrast, an inhibition of EGF receptor-mediated Raf and ERK activation was observed after stimulation of M_1 mAChRs expressed in Rat-1a fibroblasts, probably due to M_1 receptor-mediated activation of protein kinase A (PKA) following stimulation of a calcium/calmodulin-sensitive adenylyl cyclase isoform [84].

5.11 ION CHANNELS

Agonist stimulation of mAChRs modulates the activity of a large number of ion channels, by either direct or indirect mechanisms, resulting in “excitatory” or “inhibitory” effects. This subject has been the topic of several excellent reviews [9, 78, 85, 86]. The excitatory effects primarily result from the closure of different types of potassium channels but may also involve the opening of cation channels, at least in some cases. Most of the inhibitory effects are mediated by the opening of potassium channels and the closure of voltage-gated calcium channels.

5.11.1 Closure of Potassium Channels

Activation of M_1 and M_3 mAChRs has been shown to mediate the inhibition of K_M channels (M current [85]). For example, Hamilton et al. [87] demonstrated that muscarinic agonist-mediated inhibition of the M current was abolished in sympathetic ganglion neurons derived from M_1 receptor KO mice. Suppression of the M current, a voltage-dependent potassium current found in various neuronal tissues including sympathetic ganglia and cortical and hippocampal neurons, leads to an increase in neuronal excitability and facilitates repetitive spike discharges [85]. Structurally, neuronal-type M channels are predicted to be composed of a heteromeric array of KCNQ2 and KCNQ3 potassium channels [88, 89]. Suh and Hille [90] recently showed that M_1 mAChR-mediated activation of PLC initiates M current modulation and that channel recovery requires ATP and PI 4-kinase, suggesting that the breakdown of PI 4,5-bisphosphate (PIP_2) represents a key factor in M current modulation.

Agonist stimulation of mAChRs also leads to the closure of several other potassium channels, including the “small” calcium-activated potassium channel (K_{Ca} [85]). This channel is widely distributed in peripheral and central neurons and is known to generate long post-spike after-hyperpolarizations (APHs). ACh-induced inhibition of this channel represents a major component of mAChR-mediated excitation of central neurons [85]. At present, it is not entirely clear which specific mAChRs are involved in mediating this activity.

In addition, activation of mAChRs also leads to the inhibition of several other classes of neuronal potassium channels/currents, including “inward-rectifier” potassium channels (K_{IR}), fast-gating M-like currents, resting “leak” potassium currents, and several cloned potassium channels including Kv1.2. In most cases, M_1 and/or M_3 mAChRs play a predominant role in mediating the inhibition of these channels/currents [85].

5.11.2 Opening of Potassium Channels

Activation of M_2 or M_4 mAChRs can lead to the opening of G-protein-regulated inward-rectifier potassium (GIRK) channels. Neuronal GIRK channels are thought to be involved in regulating neuronal excitability by contributing to the resting potential [91]. Many of the key studies on GIRK channel regulation were performed on the cardiac K_{ACh} channel, which is composed of GIRK1 and GIRK4 subunits. This channel is directly activated by $G\beta\gamma$ subunits released following M_2 receptor-mediated activation of G proteins of the G_i family [91]. It is likely that neuronal

GIRK channels are activated by a similar mechanism [78, 85, 91]. Studies with GIRK4 KO mice have shown that the activation of cardiac K_{ACh} channels plays an important role in ACh- and adenosine-mediated bradycardia in vivo [92]. Interestingly, several studies suggest that G_q -coupled mAChRs may be able to inhibit GIRK channel activity [78].

5.11.3 Modulation of Calcium Channels

As discussed in Section 5.6, activation of the G_q -coupled mAChRs leads to pronounced increases in $[Ca^{2+}]_i$, primarily via $PLC\beta$ -mediated generation of IP_3 . However, mAChRs can also modulate $[Ca^{2+}]_i$ by regulating the activity of voltage-operated calcium channels (VOCCs) that open when the cell membrane is depolarized. The VOCC family is classified into L, N, P/Q, R, and T subtypes, and there is evidence that mAChRs can modulate the activity of all of these channels [78].

Activation of M_2 and M_4 mAChRs results in the inhibition of VOCCs [85]. This activity is probably mediated by free $G\beta\gamma$ subunits released following the activation of G_i -type G proteins and may be responsible for the well-known autoinhibitory effects of ACh on its own release observed in many neuronal tissues [85].

In sympathetic ganglion neurons, muscarinic agonists inhibit N- and L-type calcium channels through two distinct G-protein-mediated pathways [93]. Studies with mAChR KO mice showed that the fast and voltage-dependent pathway is mediated by M_2 receptors while the slow and voltage-independent pathway is mediated by M_1 receptors [93].

Interestingly, several studies suggest that the activity of several VOCC subtypes can also be enhanced following muscarinic stimulation, at least in certain tissues or cell types and under certain experimental conditions (for a detailed review of these studies, see [78]).

5.11.4 Nonselective Cation Channels

Muscarinic stimulation can also result in the opening of nonselective cation channels in several peripheral and central tissues or cell types. For example, activation of M_2 receptors is known to lead to the opening of a nonselective cation channel in smooth muscle cells, a response predicted to play a role in smooth muscle contraction [94, 95]. The activation of coexpressed smooth muscle M_3 receptors has been shown to play a permissive role in this activity [95, 96]. Muscarinic agonists can also induce the activation of nonselective cation channels in different regions of the brain [78]. Analysis of a series of mAChR KO mice showed that muscarine-induced hippocampal γ oscillations were dependent on M_1 receptor-mediated depolarization of hippocampal CA3 pyramidal neurons, involving the activation of the mixed sodium-potassium current I_h and the calcium-dependent nonspecific cation current I_{cat} [97].

5.11.5 Chloride Channels

Several reports suggest that activation of mAChRs can trigger the opening of chloride channels in various tissues. In most cases, this activity is dependent on the primary increase in $[Ca^{2+}]_i$ [78]. In salivary gland acinar cells, for example,

ACh-mediated activation of G_q -coupled mAChRs (M_1 and M_3) is predicted to stimulate fluid secretion via activation of a calcium-gated chloride channel [98].

Marsh et al. [99] identified a delayed calcium-dependent chloride channel in sympathetic ganglion cells which is induced by the synergistic action of calcium and DAG. These authors demonstrated that the increase in these two second messengers was mediated by the simultaneous activation of nicotinic AChRs (leading to a rise in $[Ca^{2+}]_i$) and mAChRs (leading to increased DAG levels), indicative of a novel form of AChR synergy.

5.12 REGULATION OF mAChR ACTIVITY

Prolonged agonist exposure of mAChRs and other GPCRs leads to an attenuation of receptor-mediated responses referred to as receptor desensitization. Molecular events closely associated with receptor desensitization are “uncoupling,” receptor internalization (sequestration), and receptor downregulation. Receptor phosphorylation events play central roles in mediating many of these processes. Several different kinases have been implicated in mAChR phosphorylation, including various GPCR kinases (GRKs), casein kinase 1 α (CK1 α), and PKC [100, 101]. The phosphorylation of mAChRs has been shown to occur on Ser and Thr residues located within the i3 loop and the cytoplasmic tail [2, 100, 101].

5.12.1 Receptor Uncoupling

The earliest phase of receptor desensitization involves receptor uncoupling in which receptors become functionally uncoupled from their G proteins. Uncoupling occurs with a very rapid time course (seconds to minutes) and may serve to quickly attenuate agonist-induced signaling to prevent overstimulation. A vast body of evidence indicates that receptor phosphorylation plays a key role in mediating this process (see Section 5.12.4).

5.12.2 Receptor Internalization

A second step associated with receptor desensitization which occurs within minutes after agonist addition is receptor internalization [100–102]. This process is defined as removal of receptors from the cell surface without concomitant loss of total cellular receptor binding sites. As has been shown for many other classes of GPCRs, agonist-induced phosphorylation of mAChRs (see Section 5.12.4) is predicted to facilitate receptor internalization [101, 103]. However, several lines of evidence suggest that agonist-induced mAChR internalization does not require the activation of heterotrimeric G proteins [101]. Moreover, the role of specific GRKs in mediating mAChR internalization depends on the specific receptor subtype and cell type studied.

Considerable evidence indicates that mAChRs, like other GPCRs, can be internalized via multiple mechanisms [100, 101]. The GPCR internalization pathway that is understood best is GRK and arrestin dependent. In this pathway, the binding of arrestin 2 and 3 (see Section 5.12.4.2) to GRK-phosphorylated receptors leads to receptor endocytosis mediated by arrestin binding to clathrin present in clathrin-coated pits [104, 105]. This internalization pathway requires the presence of the

GTPase dynamin, which is required for pinching off receptor-containing vesicles from the plasma membrane [104, 105].

Studies with transfected HEK cells have shown that M_1 , M_3 , and M_4 mAChRs internalize in an arrestin-dependent fashion via clathrin-coated vesicles [101]. However, in the same cell type, M_2 mAChR internalization occurs through an arrestin-independent mechanism [101], suggesting that phosphorylated M_2 mAChRs may be able to interact with other cellular proteins to enter an internalization pathway that is clathrin independent. Interestingly, studies involving the use of dominant-negative mutant forms of dynamin strongly suggest that dynamin plays a role in the internalization pathway used by the M_1 , M_3 , and M_4 mAChRs as well as the M_2 mAChR [101].

Biochemical studies with M_2 mAChRs expressed in cardiac myocytes have shown that M_2 receptors undergo agonist-dependent trafficking to caveolae, small flask-shaped invaginations of the plasma membrane [106]. In a secondary step, these receptor-containing caveolae are predicted to be pinched off from the plasma membrane, leading to the internalization of a significant portion of M_2 receptors [107].

The structural elements involved in mAChR internalization have been studied by mutational analysis of several mAChR subtypes [2, 101]. For example, site-directed mutagenesis studies with the M_1 mAChR have shown that most mutations that interfere with productive receptor–G protein coupling also impair M_1 mAChR internalization [108]. However, several mutant M_1 receptors were identified that were defective in G-protein coupling but were able to internalize normally [108], indicating that G-protein activation is not an absolute requirement for receptor internalization to occur. Taken together, these findings support the concept that the receptor domains involved in mAChR internalization overlap but are not identical with those critical for receptor–G protein coupling.

5.12.3 Receptor Downregulation

In contrast to receptor internalization, receptor downregulation can be observed in many cell types upon prolonged agonist exposure (hours) and is characterized by a decrease in the total number of cellular receptors [102]. Return of receptor levels to control levels requires *de novo* protein synthesis. The role of receptor internalization in GPCR downregulation is incompletely understood at present and seems to depend on the specific GPCR studied and the cellular background in which it is expressed.

In many, but not all, cases, receptor-mediated G-protein activation appears to be required for receptor downregulation to occur. Several lines of evidence suggest that the early stages of receptor downregulation are mainly due to an increased rate in receptor degradation [107], while later stages may involve decreases in receptor mRNA levels (see, e.g., [109]).

Mutational analysis of the mouse M_1 mAChR expressed in Y1 adrenal carcinoma cells [110] and the human M_2 mAChR expressed in CHO cells [111] suggests that sequences within the i3 loop play a key role in mAChR downregulation. Using stably transfected CHO cells, Shockley et al. [112] identified several point mutations in the i2 and i3 loops of the human M_1 receptor that interfered with receptor downregulation but not internalization. Moreover, studies with stably transfected CHO cells showed that three Thr residues present in the C-terminal tail domain of the human M_3 mAChR are required for proper receptor downregulation (corresponding

to residues 549, 552, and 553 in Fig. 5.1 [113]). Similarly, Goldman and Nathanson [114] found that the lone Tyr residue in the C-terminal region of the porcine M₂ mAChR (Tyr459) heterologously expressed in JEG-3 cells is involved in receptor downregulation but not in receptor internalization and G-protein coupling.

As summarized in the previous paragraph, many of the analyzed mutant mAChRs that showed deficits in downregulation did not show significant impairments in short-term receptor internalization. This observation clearly indicates that receptor internalization is not an absolute requirement for mAChR downregulation to occur.

5.12.4 Receptor Phosphorylation

Characteristically, the second-messenger-dependent protein kinases, such as PKC or PKA, are able to phosphorylate GPCRs even in the absence of agonist, suggesting that they may play a role in heterologous receptor desensitization. On the other hand, GRKs can only recognize the agonist-activated forms of GPCRs and are thought to play key roles in short-term homologous receptor desensitization.

5.12.4.1 Protein Kinase C. PKC is capable of phosphorylating mAChRs and other GPCRs in an agonist-independent fashion. It has been shown that both the M₁ and the M₃ mAChRs are phosphorylated by PKC in an agonist-independent fashion both in vitro and in vivo [101]. For example, Haga et al. [115] demonstrated that the M₁ mAChR is phosphorylated by PKC on Thr and Ser residues located within the cytoplasmic tail and the C-terminal segment of the i3 loop. Importantly, activation of PKC by phorbol esters led to impaired mAChR signaling in a number of different cell types predicted to express M₁ and/or M₃ mAChR [101]. Since stimulation of M₁ and M₃ mAChRs results in the generation of the potent PKC activator DAG, it is likely that PKC-mediated phosphorylation of these receptors serves as a negative-feedback mechanism to dampen M₁ and M₃ receptor signaling.

5.12.4.2 GPCR Kinases. GRKs play fundamental roles in the homologous desensitization of mAChRs and other GPCRs [105, 116]. In contrast to the second-messenger-activated protein kinases, GRKs only phosphorylate the agonist-activated forms of GPCRs. In mammals, the GRK family consists of seven distinct members, GRK1–7 [105, 116]. Whereas GRK1 and GRK7 are only expressed in the retina, GRK2, 3, 5, and 6 are expressed ubiquitously. GRK4 is preferentially expressed in the testes and brain. The GRK-phosphorylated receptors are able to bind to a group of proteins referred to as arrestins which prevent receptor–G protein signaling by blocking the intracellular receptor surface [104, 117]. The arrestin family consists of the two visual arrestins and arrestin 2 (β -arrestin 1) and arrestin 3 (β -arrestin 2). The latter two arrestins are expressed ubiquitously [104, 117].

In vitro and in vivo studies have shown that agonist-activated M₁–M₄ mAChRs are phosphorylated by different members of the GRK family (GRK2, 3, 5, and 6 [100, 101, 103]). Many of these studies used strategies that involved the over-expression of WT GRKs or mutant GRKs endowed with dominant-negative activity. However, it is often difficult to conclude from these studies which specific GRKs regulate the function of individual mAChRs in specific tissues or cell types in vivo [100]. Recently, novel experimental strategies including the use of GRK KO mice and

antisense approaches have been applied to overcome the difficulties associated with the use of overexpression approaches.

The M₁ and M₃ mAChRs have been shown to be phosphorylated by purified GRK2 in an agonist- and Gβγ-dependent fashion ([115, 118]; note that free Gβγ subunits are required for trafficking GRK2 and 3 to the plasma membrane). The major GRK2 phosphorylation sites of the human M₁ mAChR are predicted to be located within a segment contained within the i3 loop (amino acids 276–303 [115]). Similarly, studies with GST fusion proteins suggest that GRK2 phosphorylates the rat M₃ mAChR on multiple Ser residues located within the i3 loop (³³¹SSS³³³ and ³⁴⁸SASS³⁵¹ [119]). These authors also identified a putative Gβγ binding site in the rat M₃ mAChR (amino acids 289–330) that is located immediately N-terminal of the GRK2 target sequence.

Recent studies strongly suggest that endogenous GRK2 plays a key role in mediating agonist-induced desensitization of M₁ mAChRs expressed by rat hippocampal neurons [120]. Interestingly, the regulatory activity of GRK2 appears to be mediated by both phosphorylation-dependent and phosphorylation-independent mechanisms [120].

Studies with transfected mammalian cells have shown that the human M₃ mAChR is also subject to agonist-dependent phosphorylation by CK1α [121–123]. Consistent with this notion, coexpression of a catalytically inactive mutant of CK1α strongly inhibited agonist-induced M₃ mAChR phosphorylation [121]. Analysis of an M₃ receptor deletion mutant lacking amino acids 370–425 suggested that the putative CK1α phosphorylation sites are likely to be located within a segment of the i3 loop that is located C-terminal of the region containing the putative GRK2 phosphorylation sites (see above [122]). Following agonist stimulation, this M₃ receptor deletion mutant retained the ability to efficiently stimulate PLC but was significantly impaired in its ability to stimulate the ERK1/2 pathway [122]. These observations suggest that CK1α-mediated phosphorylation of specific intracellular M₃ receptor residues is required for the efficient activation of the ERK1/2 pathway, perhaps by allowing the recruitment of site-specific adaptor proteins [122, 123].

Willets et al. [124, 125] recently demonstrated that agonist-induced phosphorylation and desensitization of M₃ mAChRs endogenously expressed by human SH-SY5Y cells is mediated primarily by GRK6.

Studies with GRK3-deficient mice indicate that M₃ receptor signaling may be regulated by GRK3 phosphorylation *in vivo*, at least in certain tissues. Recently, Fisher et al. [126] demonstrated that methacholine-induced bronchoconstriction is completely abolished in M₃ mAChR KO mice, suggesting that mAChR-mediated airway constriction is mediated by the M₃ receptor subtype *in vivo*. Interestingly, methacholine-induced bronchoconstriction was significantly enhanced in GRK3-deficient mice [127], suggesting that airway M₃ mAChRs may be a target of GRK3 *in vivo*.

Many studies have implicated GRKs (GRK2, 3, and 5) in the phosphorylation and desensitization of the M₂ receptor subtype [100, 101, 103]. Strikingly, studies with transfected HEK293 cells showed that mutant human M₂ receptors lacking the central portion of the i3 loop (amino acids 282–323 [128]) or containing simultaneous mutational modifications of two clusters of Thr and Ser residues located within this sequence [129] were no longer subject to agonist-dependent phosphorylation and desensitization.

Studies with GRK5-deficient mice demonstrated that many of the central actions of oxotremorine, a non-subtype-selective muscarinic agonist, were enhanced or prolonged in the absence of GRK5 [130]. These responses included oxotremorine-induced hypothermia, tremor, hypolocomotion, and analgesia. Phenotypical analysis of M₂ receptor KO mice showed that these responses are mediated exclusively or predominantly by the M₂ receptor subtype [131]. These studies therefore suggest that GRK5-mediated phosphorylation leads to the desensitization of central M₂ receptors *in vivo*. A recent study using GRK5-deficient mice also indicated that the activity of bronchial M₂ mAChRs may also be regulated by GRK5 [132].

Relatively little is known about the potential roles of GRKs in regulating the functions of the M₄ and M₅ mAChR subtypes. Holroyd et al. [133] presented data suggesting that GRK2 plays a key role in mediating internalization and desensitization of M₄ mAChRs endogenously expressed by NG108-15 cells. Studies with COS-7 cells transiently expressing the human M₅ mAChR showed that agonist-induced M₅ receptor internalization was facilitated by coexpression of GRK2 [134]. However, it remains to be shown whether the M₅ receptor is indeed a direct target for GRK2-mediated phosphorylation.

5.12.5 Mechanisms Involved in mAChR Resensitization

Accumulating evidence suggests that receptor internalization and recycling to the cell surface play key roles in restoring normal signaling function to desensitized GPCRs [104]. However, several studies have shown that the precise role of receptor internalization and recycling for receptor resensitization is critically dependent on the specific GPCR being analyzed and the type of cell by which it is expressed. This concept is highlighted by the outcome of studies carried out with M₃ or M₄ mAChRs expressed in different cellular backgrounds. Whereas receptor internalization and recycling appeared to be required for receptor resensitization in some cases, these steps did not prove to be essential for the receptor resensitization in other cell types (reviewed by [101]).

5.13 mAChR DIMERIZATION

Accumulating evidence suggests that GPCRs, including different members of the mAChR family, exist in the plasma membrane as dimeric or oligomeric complexes [135–137]. Several studies demonstrated that GPCR dimerization occurs in the endoplasmic reticulum and that dimeric GPCRs, following their transport to the cell surface, may represent the basic functional receptor unit able to productively interact with heterotrimer G proteins [138].

Early radioligand-binding studies indicated that orthosteric muscarinic ligands could bind to mAChRs in a cooperative fashion, a behavior that could be explained by the existence of mAChR dimers or oligomers (see [139] and references therein). Maggio et al. [140] carried out a series of cotransfection experiments involving two M₃ muscarinic/ α_2C -adrenergic hybrid receptors none of which was able to bind muscarinic or adrenergic ligands and to couple to G_q when expressed alone in COS-7 cells. However, coexpression of the two hybrid receptors resulted in the appearance of a small but significant number of muscarinic and adrenergic binding sites, and

incubation of cotransfected cells with the muscarinic agonist carbachol led to a pronounced increase in the breakdown of PI lipids. Similar results were obtained in studies in which two different coupling-deficient mutant M_3 receptors were coexpressed in COS-7 cells [135, 140]. These findings provided strong support for the concept that M_3 mAChRs can exist in dimeric or oligomeric complexes.

Moreover, co-immunoprecipitation studies using different versions of the M_3 [141] or M_2 [142, 143] mAChRs carrying different epitope tags also confirmed the existence of mAChR homodimers/oligomers. Studies with M_2 mAChRs expressed in Sf9 insect cells suggest that M_2 receptor aggregates are at least trimeric [142, 143]. Immunoprecipitation and immunoblotting studies demonstrated that M_3 receptor dimers are expressed on the cell surface and can bind muscarinic ligands [141]. Their formation seems to involve both noncovalent as well as disulfide bond interactions between receptor monomers [141]. In transfected COS-7 cells, M_3 receptor dimerization is insensitive to regulation by ligands [141]. Similar results have been obtained with M_2 mAChRs expressed in Sf9 insect cells [142].

Based on coexpression studies analyzing various mutant M_2 and M_3 mAChRs, Maggio et al. [144] suggested the existence of M_2/M_3 receptor heterodimers endowed with a novel ligand binding pharmacology (see, however, [141]). It remains to be seen whether such mAChR heterodimers are of physiological relevance. Another set of coexpression studies involving the use of different M_3 mutant receptors as well as of M_3 muscarinic/ α_{2C} -adrenergic hybrid receptors demonstrated that muscarinic activation of the ERK1/2 pathway required the simultaneous activation of two receptor monomers contained within a dimeric receptor assembly [145]. In addition, Novi et al. [146] recently presented data suggesting that M_3 receptor-mediated recruitment of β -arrestin 1 requires the simultaneous stimulation of the two monomeric units contained within a receptor dimer.

5.14 PHENOTYPICAL ANALYSIS OF mAChR-DEFICIENT MICE

Because of the lack of ligands endowed with a high degree of receptor subtype selectivity and the fact that most tissues or cell types express two or more mAChR subtypes, identification of the physiological and pathophysiological roles of the individual mAChR subtypes has proven a difficult task. To circumvent these difficulties, we and other laboratories applied gene-targeting techniques to generate mutant mouse lines deficient in each of the five mAChR genes (for recent reviews, see [40, 147, 148]). Mutant mice lacking M_1 , M_2 , M_3 , M_4 , or M_5 mAChRs are viable and fertile, appear generally healthy, and do not display any gross behavioral or morphological abnormalities. However, detailed phenotyping studies showed that each of the five mutant mouse lines displayed characteristic physiological, pharmacological, behavioral, biochemical, or neurochemical deficits. Disruption of one specific mAChR gene does not seem to have major effects on the expression levels of the remaining four mAChRs [40, 149, 150], an observation that greatly facilitates the interpretation of results of mouse phenotyping studies.

The following paragraphs will summarize the key findings that have emerged from the phenotypical analysis of M_1 – M_5 mAChR mutant mice. Homozygous M_1 – M_5 mAChR mutant mice will be referred to as $M1R^{-/-}$ mice, $M2R^{-/-}$ mice, and so on.

5.14.1 Functions Mediated by Central mAChRs

5.14.1.1 Learning and Memory. The M_1 mAChR is abundantly expressed in higher brain areas, including hippocampus and cerebral cortex, which are known to be critically involved in cognitive processes [10, 151]. Consistent with this observation, muscarinic agonist-induced activation of the MAPK pathway was virtually abolished in primary cortical cultures [152] or CA1 hippocampal pyramidal neurons from $M1R^{-/-}$ mice [153]. Similar results were obtained in [35 S]-GTP γ S binding assays [154] and in in vitro [152] and in vivo [155] studies examining muscarinic agonist-mediated stimulation of PI hydrolysis in hippocampal and cortical preparations. These findings clearly indicated that the M_1 receptor is the functionally predominant G_q -coupled mAChR subtype expressed in the forebrain.

Based on the high expression levels of the M_1 receptor in hippocampus and cerebral cortex, together with the outcome of classical pharmacological studies using subtype-preferring mAChR antagonists, it has been speculated that M_1 receptors may play a role in mediating higher cognitive processes such as learning and memory [156, 157]. To test this hypothesis, Miyakawa et al. [158] subjected $M1R^{-/-}$ mice to several hippocampus-dependent learning and memory tasks. $M1R^{-/-}$ mice performed equally well as their WT littermates in the Morris water maze, a test which is frequently used to assess spatial reference memory in rodents. Moreover, $M1R^{-/-}$ mice displayed normal freezing levels during context testing carried out 24 h after fear conditioning and did not show any significant cognitive deficits in the eight-arm radial maze test during training with 30–120 s delay time between individual trials [158]. On the other hand, $M1R^{-/-}$ mice showed performance deficits in the eight-arm radial maze test during trials without delay and during auditory-cued and context testing carried out 48 h and four weeks, respectively, after fear conditioning [158]. However, the extent of these behavioral deficits showed a very good correlation with the degree of hyperactivity displayed by the tested $M1R^{-/-}$ mice (see Section 5.14.1.3), suggesting that the hyperactivity phenotype exhibited by the $M1R^{-/-}$ mice makes a major contribution to the observed performance deficits. Interestingly, the behavioral pattern displayed by the $M1R^{-/-}$ mice is somewhat reminiscent of human attention-deficit-hyperactivity disorder in which hyperactivity is often accompanied by cognitive deficits [159].

Anagnostaras et al. [160] recently reported that $M1R^{-/-}$ mice displayed both enhancements and impairments of distinct cognitive functions. These authors found that $M1R^{-/-}$ mice exhibited a mild reduction in hippocampal long-term potentiation (LTP) in response to theta burst stimulation (Schaffer-CA1 synapse). $M1R^{-/-}$ mice showed normal or enhanced memory for tasks that involved matching-to-sample problems (contextual fear conditioning and Morris water maze). In contrast, $M1R^{-/-}$ mice displayed significant impairments in non-matching-to-sample working memory and consolidation (win-shift radial arm and social discrimination learning). Based on these observations, Anagnostaras et al. [160] concluded that M_1 receptors are not essential for memory formation or initial stability of memory in the hippocampus but are most likely involved in processes requiring interactions between cerebral cortex and hippocampus.

In a recent study, Seeger et al. [161] examined the potential role of M_2 receptors in learning and memory and hippocampal synaptic plasticity. Interestingly, $M2R^{-/-}$ mice showed significant deficits in behavioral flexibility and working memory in the

Barnes circular maze and the T-maze delayed alternation test, respectively. Moreover, the absence of M_2 receptors led to profound changes in neuronal plasticity studied at the Schaffer-CA1 synapse using hippocampal slices. Strikingly, short-term potentiation (STP) was abolished and LTP was drastically reduced following high-frequency stimulation of $M2R^{-/-}$ hippocampi. Incubation of $M2R^{-/-}$ hippocampal slices with bicuculline, a γ -aminobutyric acid ($GABA_A$) receptor antagonist, restored STP and significantly increased LTP. This observation, together with results obtained in whole-cell recordings from CA1 pyramidal cells, suggested that the deficits in synaptic plasticity observed with $M2R^{-/-}$ hippocampi are most likely caused by enhanced GABAergic inhibition. Seeger et al. [161] also demonstrated that the persistent enhancement of excitatory synaptic transmission in CA1 pyramidal cells induced by the transient application of low concentrations of a muscarinic agonist (referred to as LTP_m [162]) was totally abolished in $M2R^{-/-}$ mice.

In vivo microdialysis studies showed that $M2R^{-/-}$ mice displayed significant changes in pharmacologically and physiologically evoked ACh release in the hippocampus, consistent with the role of presynaptic M_2 autoreceptors in mediating inhibition of hippocampal ACh release [163]. These neurochemical changes were accompanied by performance deficits in a passive avoidance test [163], suggesting that improper regulation of synaptic ACh release may also contribute to the cognitive deficits caused by the lack of M_2 receptors.

Since impaired central muscarinic signaling is associated with Alzheimer's disease and normal aging processes [164], these findings should be of considerable therapeutic relevance.

5.14.1.2 Epileptic Seizures. Hamilton et al. [87] examined the ability of pilocarpine, a non-subtype-selective muscarinic agonist, to induce epileptic seizures in WT and $M1R^{-/-}$ mice. Whereas pilocarpine consistently elicited seizures in WT mice, it was completely devoid of seizure activity in $M1R^{-/-}$ mice. The lack of M_2 – M_5 receptors did not interfere with pilocarpine-induced seizure responses [155]. These results raise the possibility that increased signaling through central M_1 receptors may play a role in the pathophysiology of at least certain forms of epileptic seizures.

5.14.1.3 Locomotor Activity. Interestingly, $M1R^{-/-}$ mice showed a pronounced increase in locomotor activity that was consistently observed in all tests that included locomotor activity measurements [158]. Gerber et al. [165] reported that the hyperactivity phenotype of the $M1R^{-/-}$ mice was associated with a significant increase (approximately two-fold) in extracellular dopamine concentrations in the striatum, most probably due to an increase in dopamine release. It remains unclear at present whether this activity is mediated by intra- or extrastriatal M_1 receptors. Independent of the precise mechanism by which the lack of M_1 receptors leads to an increase in locomotor activity and striatal dopamine release, these findings suggest that centrally active, selective M_1 mAChR antagonists are potentially useful in the treatment of Parkinson's disease, a brain disorder characterized by drastically reduced striatal dopamine levels. Since schizophrenia is associated with increased dopaminergic transmission in various forebrain areas, improper signaling through M_1 receptors may contribute to the pathophysiology of certain forms of schizophrenia [165].

M4R^{-/-} mice also displayed a small but statistically significant increase in basal locomotor activity [166]. Interestingly, the locomotor stimulation observed after administration of a centrally active D1 dopamine receptor agonist was greatly enhanced in M4R^{-/-} mice [166]. In the striatum, M₄ mAChRs are coexpressed with D1 dopamine receptors by striatal projection neurons which give rise to the so-called direct striatonigral pathway activation which facilitates locomotion [167]. The findings by Gomez et al. [166] therefore suggest that striatal M₄ receptors exert an inhibitory effect on D1 receptor-stimulated locomotor activity. Since functional interactions between striatal cholinergic and dopaminergic pathways play a key role in extrapyramidal motor control [167], these observations are of potential relevance for the treatment of Parkinson's disease and related movement disorders.

5.14.1.4 Analgesia. Administration of centrally active muscarinic agonists induces robust analgesic effects which are dependent on both spinal and supraspinal mechanisms [168–170]. Using the tail-flick and hot-plate analgesia tests, Gomez et al. [131, 166] examined whether muscarinic agonist-induced analgesic responses were altered in M2R^{-/-} and M4R^{-/-} mice. These studies showed that the analgesic potency of oxotremorine administered systemically (s.c.) was markedly reduced (but not abolished) in M2R^{-/-} mice [131] but remained nearly unchanged in M4R^{-/-} mice [166]. Similar responses were observed after intrathecal (i.t.) or intracerebroventricular (i.c.v.) administration of oxotremorine [171]. Strikingly, oxotremorine was virtually devoid of analgesic activity in M2R^{-/-}/M4R^{-/-} double-KO mice [171], independent of the route of application (s.c., i.t., or i.c.v.). These findings indicate that both M₂ receptors (which functionally predominate) and M₄ receptors are involved in mediating the analgesic effects of muscarinic agonists at the spinal and supraspinal levels. Most likely, the antinociceptive effects mediated by M₄ receptors remained undetected in the M4R^{-/-} mice [166] due to the presence of the functionally predominant M₂ receptor. Radioligand binding studies with spinal cord tissues from WT and mAChR mutant mice suggested that ~90% of all mAChRs in the spinal cord represent M₂ receptors [171]. The precise mechanisms by which spinal and supraspinal M₂ and M₄ receptors mediate their analgesic effects remain to be elucidated.

Duttaroy et al. [171] also reported that two novel muscarinic agonists chemically derived from epibatidine, CMI-936 and CMI-1145 [172], showed significantly higher affinity (~6–16-fold) for M₄ than for M₂ receptors and displayed reduced analgesic activity in both M2R^{-/-} and M4R^{-/-} mice, independent of the route of application. Consistent with the outcome of the analgesia experiments, [³⁵S]GTPγS binding studies using tissues from different mAChR mutant mice also demonstrated the existence of a small but functionally significant M₄ receptor population in the mouse spinal cord [173]. Since M₄ receptors, unlike M₂ receptors, do not seem to mediate important peripheral functions, the potential use of selective M₄ receptor agonists as novel analgesic agents is unlikely to be associated with any significant peripheral side effects. It should also be noted that the potential use of muscarinic agonists as analgesic drugs is probably less likely to lead to tolerance and addiction associated with the use of classical opioid analgesics [170, 174].

5.14.1.5 Muscarinic Agonist-induced Tremor and Hypothermia. Systemic administration of oxotremorine or other centrally active muscarinic agonists causes

whole-body tremor and pronounced hypothermic effects. Strikingly, Gomeza et al. [131] found that oxotremorine-mediated tremor was totally abolished in $M2R^{-/-}$ mice. Pharmacological antagonism of oxotremorine-induced tremor activity has often been used as a model system for identifying new anti-Parkinson drugs. The findings by Gomeza et al. [131] therefore suggest that drugs originating from this screening procedure were selected based on their ability to block central M_2 receptors.

Moreover, oxotremorine-induced hypothermic responses were significantly reduced but not abolished in $M2R^{-/-}$ mice [131], suggesting that both M_2 and non- M_2 mAChRs may play a role in cholinergic regulation of body temperature.

5.14.1.6 Role of M_3 mAChRs in Stimulating Food Intake. Yamada et al. [175] reported that $M3R^{-/-}$ mice showed a pronounced reduction in body weight (by $\sim 25\%$) that was associated with a significant decrease in the mass of peripheral fat pads and greatly reduced serum leptin and insulin levels. Food intake studies showed that $M3R^{-/-}$ mice consumed considerable less food than their WT littermates [175]. Analysis of the expression levels of various hypothalamic neuropeptides known to play key roles in the regulation of appetite showed that $M3R^{-/-}$ mice displayed greatly reduced expression levels of melanin-concentrating hormone (MCH). MCH is virtually exclusively expressed in so-called second-order neurons of the lateral hypothalamus and is normally increased in fasted mice or under conditions of leptin deficiency [176]. Interestingly, MCH-containing neurons express M_3 receptors [175], and muscarinic stimulation increases hypothalamic MCH expression [177]. Yamada et al. [175] also showed that i.c.v. administration of the appetite-stimulating, agouti-related peptide, which is known to stimulate the activity of MCH-containing hypothalamic neurons [176], failed to stimulate food intake in $M3R^{-/-}$ mice. Taken together, these observations suggest that activation of hypothalamic M_3 receptors expressed by MCH neurons plays a role in the stimulation of food intake. Pharmacological manipulation of this hypothalamic cholinergic pathway may therefore represent a novel strategy for the control of food intake. It should be noted, however, that M_3 receptors are also widely expressed in peripheral organs including smooth muscle and glandular tissues. Thus, additional studies are needed to assess the relative contribution of central versus peripheral deficits to the hypophagia phenotype displayed by the $M3R^{-/-}$ mice.

5.14.1.7 Central Muscarinic Autoreceptors. ACh, like many other neurotransmitters, can inhibit its own release via stimulation of so-called inhibitory autoreceptors present on cholinergic nerve endings [178]. Using superfused hippocampal, cortical, and striatal slices that had been preincubated with [3 H]choline to label cellular ACh pools, Zhang et al. [179] demonstrated that autoinhibition of ACh release is mediated predominantly by M_2 receptors in the mouse hippocampus and cerebral cortex, but primarily by M_4 receptors in the mouse striatum. Since the proper regulation of ACh release in these tissues is thought to be critically involved in various fundamental functions of the CNS, including cognition and locomotor control, these findings should be of high clinical relevance.

5.14.1.8 Modulation of Striatal Dopamine Release. Activation of striatal mAChRs is known to stimulate dopamine release in the striatum [180, 181]. Studies with superfused striatal slices demonstrated that oxotremorine-mediated potentiation of

potassium-stimulated [^3H]dopamine release was abolished in $\text{M4R}^{-/-}$ mice, significantly increased in $\text{M3R}^{-/-}$ mice, and significantly reduced (but not abolished) in $\text{M5R}^{-/-}$ mice [182, 183]. Additional studies suggested that the dopamine release-stimulating M_4 receptors are probably located on neuronal cell bodies but that the release-facilitating M_5 and the release-inhibiting M_3 receptors are most likely located on nerve terminals [183]. Pharmacological blockade of striatal GABA_A receptors suggested that M_3 and M_4 receptors mediate their dopamine release-modulatory effects via facilitation or inhibition, respectively, of striatal GABA release [183]. Since striatal dopaminergic signaling is severely impaired in Parkinson's disease, these findings should be of considerable therapeutic interest.

5.14.1.9 Suppression of Inhibitory Hippocampal Synapses. Electrophysiological studies carried out with hippocampal neurons prepared from different mAChR single- and double-KO mice recently identified two distinct mechanisms by which muscarinic activation can suppress inhibitory synaptic transmission in the hippocampus [184, 185]. Activation of M_2 mAChRs located on presynaptic terminals was found to be required for the suppression of GABA release in a cannabinoid receptor type 1 (CB1)–independent fashion [185]. Additional evidence suggested that activation of a mixture of postsynaptic M_1 and M_3 mAChRs facilitates the depolarization-induced release of endocannabinoids which are predicted to suppress GABA release via activation of presynaptic CB1 receptors [184, 185].

5.14.1.10 M_4 Receptor-mediated Regulation of Prepulse Inhibition and Haloperidol-Induced Catalepsy. Phenotypical analysis of $\text{M4R}^{-/-}$ mice suggested that central M_4 receptors play a role in modulating prepulse inhibition (PPI) of the startle reflex, a measure of attention [186]. Specifically, Felder et al. [186] demonstrated that $\text{M4R}^{-/-}$ mice displayed a significant increase in sensitivity to the PPI-disrupting effect of the psychomimetic phencyclidine, a noncompetitive *N*-methyl-d-aspartate (NMDA) receptor antagonist. Since phencyclidine-mediated disruption of PPI is frequently used as an animal model of psychosis, central M_4 receptors may represent a novel drug target for the treatment of schizophrenia and related neurological disorders.

In a recent study, Karasawa et al. [187] examined the ability of the muscarinic antagonist scopolamine to suppress the cataleptic responses induced by the D2-type dopamine receptor antagonist haloperidol in WT and $\text{M4R}^{-/-}$ mice. While scopolamine abolished haloperidol-induced catalepsy in WT mice, it had little effect on haloperidol-mediated cataleptic responses in $\text{M4R}^{-/-}$ mice [187]. Since haloperidol-induced catalepsy is often used as an animal model to mimic the extrapyramidal motor side effects caused by antipsychotic drugs, these findings suggest that selective blockade of M_4 receptors may be beneficial in treating the extrapyramidal symptoms in Parkinson's disease and related movement disorders.

5.14.1.11 Role of M_4 and M_5 Receptors in Modulating Dopamine Efflux in Nucleus Accumbens. Forster et al. [188] demonstrated that electrical stimulation of the laterodorsal tegmental nucleus, a mesopontine nucleus that provides the major source of cholinergic input to the dopamine-containing neurons of the ventral tegmental area (VTA [189]), triggers a three-phasic pattern of changes in dopamine efflux in the nucleus accumbens (nAcc) of WT mice. Strikingly, the long-lasting

increase in dopamine levels in the nAcc (phase III) was selectively abolished in M5R^{-/-} mice [188]. This neurochemical deficit is most likely caused by the lack of excitatory M₅ receptors expressed by the dopamine-containing VTA neurons which predominantly express the M₅ mAChR subtype [19].

In another in vivo microdialysis study, Tzavara et al. [190] showed that basal dopamine levels were significantly increased in the nAcc of M4R^{-/-} mice. Enhanced dopamine efflux in the nAcc of M4R^{-/-} mice was also observed after administration of the psychostimulants *d*-amphetamine and phencyclidine [190]. These neurochemical alterations were associated with significantly increased basal ACh levels in the midbrain of M4R^{-/-} mice. Moreover, in the absence of M₄ receptors, the enhancement of midbrain ACh efflux in response to scopolamine was markedly reduced [190]. These findings are consistent with the concept that the absence of inhibitory midbrain M₄ autoreceptors is responsible for the enhanced dopamine efflux in the nAcc of M4R^{-/-} mice, probably due to increased excitatory cholinergic flow to midbrain dopaminergic neurons. Centrally active M₄ receptor agonists may therefore become clinically useful in the treatment of CNS disorders associated with hyperdopaminergia.

5.14.1.12 Role of M₅ Receptors in Modulating Rewarding Effects of Drugs of Abuse. Consistent with the observation that activation of mesolimbic M₅ receptors facilitates dopamine release in the nAcc [188], behavioral studies demonstrated that M5R^{-/-} mice showed reduced sensitivity to the rewarding effects of morphine and cocaine [191, 192]. In addition, the severity of morphine and cocaine withdrawal symptoms was shown to be reduced in M5R^{-/-} mice [191, 192]. These behavioral deficits were associated with distinct biochemical changes in the nAcc, including a reduction in morphine-stimulated dopamine efflux and Fos-B expression [191]. Taken together, these findings suggest that centrally active M₅ receptor antagonists may become therapeutically useful for the treatment of drug addiction.

5.14.2 Functions Mediated by Peripheral mAChRs

5.14.2.1 Smooth Muscle. Studies with isolated smooth muscle tissues from M3R^{-/-} mice demonstrated that M₃ mAChRs play a predominant role in mediating muscarinic agonist (ACh)-induced smooth muscle contractions [40, 148], consistent with the outcome of a large number of pharmacological studies [193]. For example, in vitro studies showed that smooth muscle tissues (urinary bladder, ileum, stomach fundus, trachea, and gallbladder preparations) derived from M3R^{-/-} mice exhibited significantly reduced maximum contractile responses (*E*_{max}) following addition of the cholinergic agonist carbachol [194–196]. However, the extent of reduction in *E*_{max} values differed significantly among tissues, ranging from only ~40% in tracheal smooth muscle [195] to >90% in urinary bladder [194].

In vivo studies showed that M3R^{-/-} mice had enlarged pupils [194], indicating that the tone of the pupillary sphincter muscle is maintained by tonic activation of M₃ receptors. However, M3R^{-/-} mice retained a weak light reflex, and atropine was able to further increase pupil size in M3R^{-/-} mice [194], suggesting that non-M₃ mAChRs also contribute to modulating ocular smooth muscle contractility. Male but not female M3R^{-/-} mice also exhibited severely distended urinary bladders [194]. However, in vivo studies demonstrated that gastrointestinal function including

food transit time is normal in $M3R^{-/-}$ mice [175, 194], suggesting that the presence of M_3 receptors is not essential for gastrointestinal motor activity in vivo.

Stengel et al. [197] showed that carbachol was about twofold less potent in contracting isolated smooth muscle preparations from stomach fundus, urinary bladder, and trachea from $M2R^{-/-}$ mice, as compared to the corresponding WT preparations. Strikingly, Matsui et al. [198] reported that carbachol-mediated contractions were almost completely abolished in ileal and urinary bladder preparations from mice deficient in both M_2 and M_3 mAChRs ($M2R^{-/-}/M3R^{-/-}$ mice). This observation strongly suggests that muscarinic agonist-mediated smooth muscle contractions are mediated by a mixture of M_3 receptors (which clearly predominate functionally) and M_2 receptors.

In a related study, Struckmann et al. [199] demonstrated that cholinergic constriction of murine peripheral airways is also mediated by a mixture of M_3 and M_2 receptors. This study also revealed the existence of pulmonary M_1 receptors whose activation counteracts cholinergic bronchoconstriction. Interestingly, a recent in vivo study showed that vagally or muscarinic agonist (methacholine)-induced bronchoconstrictor responses were abolished in $M3R^{-/-}$ mice [126]. Given the important role of muscarinic cholinergic mechanisms in pulmonary disease, these findings should be of considerable therapeutic relevance.

Matsui et al. [200] recently reported that the relaxant effects of forskolin were enhanced in different smooth muscle tissues from $M2R^{-/-}$ mice stimulated with the muscarinic agonist oxotremorine-M. This observation suggests that stimulation of smooth muscle M_2 receptors can counteract the relaxant effects of agents that increase cAMP levels, probably via M_2 receptor-induced activation of G proteins of the G_i family which mediate the inhibition of adenylyl cyclase. Taken together, these data indicate that M_2 receptors facilitate smooth muscle contractility through both direct and indirect mechanisms. In addition, a recent study using ileal segments prepared from $M2R^{-/-}$ and $M3R^{-/-}$ mice strongly suggested that muscarinic agonist-induced short-term heterologous desensitization of intestinal smooth muscle requires the simultaneous activation of both M_2 and M_3 mAChRs [201].

5.14.2.2 Salivary Secretion. Pharmacological evidence suggests that M_3 mAChRs play an important role in mAChR-mediated salivation [9]. Consistent with this concept, Matusi et al. [194] reported that injection of a single low dose of pilocarpine (1 mg/kg, s.c.) induced salivation in WT mice but failed to do so in $M3R^{-/-}$ mice. However, subsequent studies showed that administration of higher doses of pilocarpine led to pronounced salivation responses in $M3R^{-/-}$ mice [149, 175, 202]. Gautam et al. [149] recently showed that pilocarpine-induced salivation responses were abolished in $M1R^{-/-}/M3R^{-/-}$ double-KO mice. Similar results were obtained by Nakamura et al. [202] studying an independently generated $M1R^{-/-}/M3R^{-/-}$ mutant mouse line. Taken together, these studies support the concept that cholinergic stimulation of salivary flow is mediated by a mixture of M_1 and M_3 receptors and that other mAChRs do not contribute to this activity to a significant extent.

5.14.2.3 Insulin and Glucagon Secretion from Pancreatic Islets. Pancreatic mAChRs play an important role in stimulating insulin secretion from pancreatic β cells [203]. Studies with isolated pancreatic islets prepared from WT and $M3R^{-/-}$ mice recently

showed that muscarinic agonist-mediated enhancement of glucose-dependent insulin release was abolished in $M3R^{-/-}$ mice [204, 205]. Duttaroy et al. [204] also demonstrated that muscarinic agonist-induced glucagon release (glucagon is expressed by pancreatic α cells) was also greatly diminished in islets from $M3R^{-/-}$ mice. These findings indicate that strategies aimed at enhancing the activity of β -cell M_3 receptors or M_3 receptor-regulated downstream signaling components may represent a useful novel approach to promote insulin release in type 2 diabetes.

5.14.2.4 Amylase Secretion from Exocrine Pancreas. Activation of pancreatic mAChRs also plays an important role in stimulating the secretion of digestive enzymes from the exocrine pancreas. Gautam et al. [150] recently showed that carbachol-induced stimulation of amylase secretion was significantly impaired in pancreatic acinar preparations from both $M1R^{-/-}$ and $M3R^{-/-}$ receptor single-KO mice and completely abolished in acinar preparations from $M1R^{-/-}/M3R^{-/-}$ double-KO mice. However, another pancreatic secretagogue, bombesin, retained its ability to fully stimulate amylase secretion in acinar preparations from $M1R^{-/-}/M3R^{-/-}$ double-KO mice. Carbachol was significantly less potent in stimulating amylase release in acinar preparations from $M3R^{-/-}$ than from $M1R^{-/-}$ mice [150], suggesting that the M_3 receptor plays a predominant role in mediating pancreatic exocrine secretion. These studies support the concept that cholinergic stimulation of pancreatic amylase secretion is mediated by a mixture of M_1 and M_3 mAChRs and that other mAChR subtypes do not make a significant contribution to this activity.

5.14.2.5 Gastric Acid Secretion. mAChRs are known to play an important role in the regulation of gastric acid secretion. Studies with $M3R^{-/-}$ mice showed that M_3 receptor activity is essential for the basal secretion of gastric acid and the trophic response of the oxyntic mucosa to gastrin [206]. Moreover, gastric acid output in response to administration of carbachol, histamine, or gastrin was significantly reduced in $M3R^{-/-}$ mice [206]. On the other hand, the lack of M_1 receptors had no significant effect on the magnitude of these responses [207]. Surprisingly, $M5R^{-/-}$ mice showed a reduction in both carbachol-mediated gastric acid secretion and carbachol-induced histamine release [207]. Since M_5 receptor mRNA was found in the stomach but not in the fundic or antral mucosa, Aihara et al. [207] concluded that gastric acid secretion is mediated by activation of M_3 receptors located on gastric parietal cells and of M_5 receptors present in the gastric submucosal plexus.

5.14.2.6 Cardiovascular System

5.14.2.6.1 Heart. ACh released from cardiac vagal nerve endings interacts with mAChRs located in the sinoatrial node to trigger a reduction in heart rate [9]. In vitro studies showed that carbachol-mediated bradycardic responses were completely abolished in isolated spontaneously beating atria prepared from $M2R^{-/-}$ mice [197]. Moreover, a recent in vivo study demonstrated that vagally or muscarinic agonist (methacholine)-induced reductions in heart rate were also absent in $M2R^{-/-}$ mice [126]. Taken together, these studies provide unambiguous evidence that the negative chronotropic effects following vagal stimulation are mediated by M_2 mAChRs and that other mAChRs do not make a significant contribution to the regulation of heart rate.

5.14.2.6.2 Blood Vessels. ACh is able to dilate most vascular beds by interacting with mAChRs located on vascular endothelial cells [208, 209]. Interestingly, Yamada et al. [182] reported that ACh virtually lost the ability to dilate cerebral arteries (basilar artery) and arterioles (pial vessels) prepared from $M5R^{-/-}$ mice, suggesting that ACh relaxes cerebral arteries and arterioles via stimulation of endothelial M_5 receptors. Since neuronally released ACh plays a role in the regulation of cerebral vascular resistance and regional blood flow [210, 211], cerebrovascular M_5 mAChRs may therefore represent an attractive novel therapeutic target for the treatment of a variety of cerebrovascular disorders, including Alzheimer's disease and certain forms of cerebral ischemia.

On the other hand, analysis of mAChR mutant mice showed that the ACh-induced relaxation of coronary arteries and the aorta is mediated predominantly by the M_3 receptor subtype [212, 213].

5.14.2.6.3 Cardiovascular Effects of McN-A-343. Systemic administration of McN-A-343, a muscarinic agonist that can activate M_1 mAChRs located on postsynaptic sympathetic ganglion neurons with high efficacy [214], caused stimulatory cardiovascular effects in WT mice but failed to do so in $M1R^{-/-}$ mice [215]. This observation convincingly demonstrates that McN-A-343 mediates its stimulatory cardiovascular effects via activation of M_1 receptors.

5.14.2.7 Peripheral Muscarinic Autoreceptors and Heteroreceptors. Recently, mAChR mutant mice have also served as tools to identify the mAChR subtypes involved in mediating autoinhibition of ACh release in various peripheral tissues. Zhou et al. [216] demonstrated that the mAChRs mediating autoinhibition of ACh release in mouse heart atria represent a mixture of M_4 and non- M_4 (probably M_2) receptors. In the mouse urinary bladder, autoinhibition of ACh release was found to be mediated predominantly by M_4 receptors [216]. Takeuchi et al. [217] showed that autoinhibition of ACh release from the mouse longitudinal muscle/myenteric plexus preparation is mediated by a mixture of M_2 and M_4 mAChRs.

A recent study examining neurotransmitter release from phrenic diaphragm preparations of WT and $M2R^{-/-}$ mice demonstrated that the inhibitory muscarinic autoreceptors present on peripheral cholinergic motor nerves represent M_2 receptors [218]. These authors also provided data suggesting that presynaptic M_2 receptors play a role in controlling the time course of ACh release from the terminals of cholinergic motor neurons [218].

Activation of mAChRs located on peripheral sympathetic nerve terminals (so-called muscarinic heteroreceptors) results in the inhibition of norepinephrine release [219]. To study the molecular identity of these muscarinic heteroreceptors, Trendelenburg et al. [220] examined various peripheral preparations from WT and mAChR mutant mice. Specifically, these investigators determined electrically evoked [3 H]norepinephrine release using cardiac (atrial), urinary bladder, and vas deferens tissues from WT, $M2R^{-/-}$, and $M4R^{-/-}$ mice. This analysis showed that the release-inhibitory muscarinic heteroreceptors represent mixtures of M_2 and non- M_2 receptors in all three tissues studied. Whereas the non- M_2 heteroreceptors present in the vas deferens are likely to represent primarily M_4 receptors, the identity of the non- M_2 heteroreceptors present in heart atria and urinary bladder remains uncertain [220].

5.14.2.8 Role of M_1 mAChRs in Development of Cytolytic T Cells. Several lines of evidence suggest that ACh plays an immunoregulatory role by modulating the function of T lymphocytes (see [221] and references therein). Zimring et al. [221] recently showed that activation of mAChRs can trigger the generation of $CD8^+$ cytolytic T lymphocytes. Interestingly, $CD8^+$ T cells prepared from $M1R^{-/-}$ mice showed a defect in the ability to differentiate into cytolytic T lymphocytes, whereas $CD8^+$ T cells from other mAChR mutant mice responded normally [221]. These findings support the novel concept that M_1 mAChRs play a role in the development of cytolytic T cells.

5.14.2.9 Functions of mAChRs in Skin. Multiple mAChR subtypes are known to be expressed by different cell types of the skin [222, 223]. Studies with $M3R^{-/-}$ mice including the use of M_3 receptor antisense oligonucleotides suggested that M_3 mAChRs play a role in mediating skin keratinocyte adhesion, most probably by modulating cadherin and catenin levels and activities [224]. Moreover, in vitro and in vivo studies with mAChR mutant mice demonstrated that keratinocyte migration and wound reepithelialization are facilitated by activation of M_4 and inhibited by activation of M_3 mAChRs [223]. These findings may lead to the development of novel therapeutic strategies useful for promoting wound healing.

Activation of mAChRs present on peripheral nociceptors of the skin can suppress the transmission of pain impulses [225, 226]. Strikingly, muscarine-induced peripheral antinociception was abolished in $M2R^{-/-}$ but not significantly affected in $M4R^{-/-}$ mice, as shown in electrophysiological and neurochemical studies using skin and skin-saphenous nerve preparations [227]. It is possible that activation of these peripheral M_2 receptors contributes to the analgesic responses observed after systemic administration of muscarinic agonists (see Section 5.14.1.4).

5.15 CONCLUSIONS

Studies with M_1 – M_5 mAChR single-KO and various mAChR double-KO strains have led to a wealth of novel information about the physiological and pathophysiological roles of the individual mAChR subtypes. The development of a new generation of mAChR mutant mice in which specific receptor subtypes can be inactivated in a tissue-specific and/or time-dependent fashion should provide even more powerful research tools. These studies should pave the way towards the development of novel strategies for the treatment of a variety of important pathophysiological conditions including pain, obesity, diabetes, and various disorders of the CNS.

ACKNOWLEDGMENTS

I would like to thank all my present and past co-workers who carried out many of the studies reviewed in this chapter. I apologize to those individuals whose work I was unable to review in this chapter because of space constraints.

Norepinephrine (noradrenaline) is a neurotransmitter in both the peripheral and central nervous systems. Epinephrine (adrenaline) is a hormone released from the adrenal gland. Norepinephrine and epinephrine are catecholamines, because they have both the catechol moiety (two hydroxyl groups on a benzene ring) and an amine (NH_2) (see Fig. 6.1). Both of these catecholamine messengers play important roles in the regulation of diverse physiological systems by acting through adrenergic receptors. Stimulation of adrenergic receptors by catecholamines released in response to activation of the sympathetic autonomic nervous system results in a variety of effects such as increased heart rate, regulation of vascular tone, and bronchodilation. In the central nervous system (CNS), adrenergic receptors are involved in many functions, including memory, learning, alertness, and the response to stress.

Figure 6.1 Molecular structures of norepinephrine and epinephrine.

6.1 HISTORICAL PERSPECTIVE

Epinephrine was first isolated from the adrenal gland in the late 1890s (later shown to be as a benzoyl derivative) by John Jacob Abel, who is the father of American pharmacology and is generally credited with isolation of the first hormone [1]. A few years later, epinephrine was isolated as the free base (later shown to be contaminated with norepinephrine) by Jokichi Takamine. Norepinephrine was synthesized in 1904 by Friedrich Stolz, who also made the first observations on its biological properties; it was as active as epinephrine in raising the blood pressure of animals but less toxic [2]. Little interest was shown in norepinephrine at that time, but two years later it was demonstrated that it possessed remarkable pressor actions and had a lower toxicity compared with epinephrine.

Starting in the 1920s Cannon attempted to identify the chemical transmitter of the sympathetic nervous system (which he called sympathin) and mistakenly concluded in 1933 that there were two sympathins, sympathin E (excitatory) and sympathin I (inhibitory) [3]. This was due in part to the fact that he was using a natural preparation, adrenaline, which at that time was a variable mixture of epinephrine and norepinephrine. It was not until the late 1940s that von Euler finally established that norepinephrine was the predominant postganglionic neurotransmitter of the sympathetic nervous system [4], for which he was awarded the Nobel Prize in 1970.

In the early 1960s Julius Axelrod, who was studying the metabolic fate of norepinephrine, injected the recently available [^3H]norepinephrine into rats and cats. He noted that the radioactivity concentrated in tissues enriched in sympathetic nerve endings but that lesions of the sympathetic nerves abolished the accumulation. Based on these observations, Axelrod then showed that norepinephrine is inactivated by a “reuptake” system that involves the transmitter being pumped back into the nerve ending that had released it [5]. Neurotransmitter inactivation had been thought to be primarily enzymatic (based on acetylcholine), but it soon became evident that reuptake was the main route of inactivation for most neurotransmitters. Axelrod also discovered that drugs such as cocaine and imipramine inhibited the reuptake of norepinephrine [6]. For his elucidation of the reuptake process Axelrod was awarded the Nobel Prize, also in 1970.

Adrenergic receptors were originally divided into two major types, α and β , based on their pharmacological characteristics (i.e., rank-order potency of agonists) [7]. Subsequently, it became apparent that there were actually three major types (Fig. 6.2), α_1 , α_2 and β [8], each of which has three subtypes. Adrenergic receptors belong to the superfamily of seven-transmembrane receptors, which consist of a

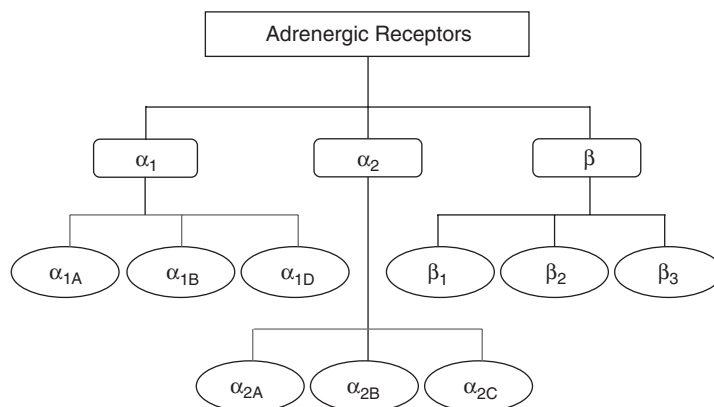

Figure 6.2 Classification scheme for adrenergic receptors. (Reprinted from [7a].) (See color insert.)

single polypeptide chain with seven hydrophobic regions that are thought to form α helical structures and span or transverse the membrane. According to the official nomenclature of the International Union of Basic and Clinical Pharmacology (IUPHAR) as determined by the IUPHAR Committee on Receptor Nomenclature and Drug Classification, the adrenergic receptors are classified as 2.1 ADR [9]. The 2.1 means that they are in the rhodopsin subclass of the seven-transmembrane receptor superfamily (or main receptor structure class). The ADR is the receptor family code for norepinephrine/epinephrine (noradrenaline/adrenaline).

Because the mechanism of action of adrenergic receptors includes the activation of guanine nucleotide regulatory binding proteins (G proteins), they are also called G-protein-coupled receptors (GPCRs). The binding of norepinephrine (or another agonist) to an adrenergic receptor induces (or stabilizes) a conformational change which allows the receptor to interact with and activate a G protein. The activated receptor facilitates the exchange of guanosine diphosphate (GDP) for guanosine triphosphate (GTP), leading to the dissociation of the α and $\beta\gamma$ subunits of the G protein, which in turn stimulate or inhibit the activity of various effectors (Fig. 6.3). Importantly, each of the three types of adrenergic receptors couples to a distinct class of G proteins: α_1 to G_q ; α_2 to $G_{i/o}$, and β to G_s . In addition to G proteins, adrenergic receptors interact with other signaling proteins and pathways such as those involving tyrosine kinases.

The β -adrenergic receptors were subdivided into β_1 (2.1.ADR.7.B1) and β_2 (2.1.ADR.8.B2) subtypes [10]. The β_1 -adrenergic receptor, the dominant receptor in heart and adipose tissue, is equally sensitive to epinephrine and norepinephrine, whereas the β_2 -adrenergic receptor, responsible for relaxation of vascular, uterine, and airway smooth muscle, is less sensitive to norepinephrine as compared to epinephrine. Subsequently it became apparent that not all of the β -adrenergic receptor-mediated responses could be classified as either β_1 or β_2 , suggesting the existence of at least one additional β subtype [11]. The β_3 receptor (2.1.ADR.9.B3) is insensitive to the commonly used β -adrenergic receptor antagonists and was previously referred to as the “atypical” β -adrenergic receptor [12]. A β_4 receptor

Figure 6.3 A GPCR and its signaling pathways. GPCRs can couple to a variety of heterotrimeric G proteins that are assembled from α (1 of 16), β (1 of 5) and γ (1 of 7) subunits. After G-protein coupling the G protein dissociates into α and $\beta\gamma$ subunits. The α and the $\beta\gamma$ subunits can modulate the activity of a variety of effector proteins—for example, adenylate cyclase, phospholipase A_2 , phospholipase C, or ion channels. (From [9a].) (See color insert.)

has been postulated; however, definitive evidence of its existence is lacking, and it is now thought to be a “state” of the β_1 adrenergic receptor [13].

The α -adrenergic receptors were first subdivided into postsynaptic (α_1) and presynaptic (α_2) subtypes [14]. After it was realized that not all α receptors with α_2 pharmacological characteristics were presynaptic (or prejunctional), the pharmacological definition was used [15]. Three genetic and four pharmacological α_2 adrenergic receptor subtypes have been defined. The evidence for α_2 receptor subtypes initially came from binding and functional studies in various tissues and cell lines [16]. The α_{2A} (2.1.ADR.4.A2A) and α_{2B} (2.1.ADR.5.A2B) subtypes were initially defined based on their differential affinity for adrenergic agents such as prazosin and oxymetazoline [17]. These subtypes were subsequently cloned from human, rat, mouse, and other species. A third subtype, α_{2C} (2.1.ADR.6.A2C), was identified originally in an opossum kidney cell line [18] and has also been cloned from several species. A fourth pharmacological subtype, the α_{2D} , was first identified in the rat and cow [19, 20]. This pharmacological subtype is a species ortholog of the human α_{2A} subtype and thus is not considered to be a separate genetic subtype.

Three genetic and four pharmacological α_1 -adrenergic receptor subtypes have also been defined [21]. The evidence for α_1 receptor subtypes initially came from binding and functional studies in various tissues and cell lines. The α_{1A} (2.1.ADR.1.A1A) and α_{1B} (2.1.ADR.2.A1B) subtypes were initially defined based on their differential affinity for adrenergic agents such as WB4101 and phentolamine [22] and their differential sensitivities to the site-directed alkylating agent chloroethylclonidine [23]. The α_{1B} subtype was subsequently cloned from the hamster and the α_{1A} was cloned from bovine brain, although it was originally called the α_{1C} -adrenergic receptor. A third subtype, α_{1D} (2.1.ADR.3.A1D) adrenergic receptor was subsequently cloned from the rat cerebral cortex, although this clone was originally called the α_{1a} -adrenergic receptor by some workers [21]. A fourth pharmacological subtype, the α_{1L} , has been identified in vascular tissues from several species [24] but may represent a conformational state of the α_{1A} receptor [25]. The current classification scheme includes the α_{1A} , the α_{1B} , and the α_{1D} , but there is no α_{1C} .

6.2 PHYSIOLOGY

Norepinephrine is a direct-acting sympathomimetic with pronounced effects on α_1 - and α_2 -adrenergic receptors and less marked effects on β -adrenergic receptors. Epinephrine, by contrast, has important β -adrenergic effects, particularly at lower concentrations. The effects of norepinephrine and epinephrine are primarily but not entirely excitatory, as reflected in the physical and mental arousal such as that seen in the fight-or-flight response. Norepinephrine is stored in granules in adrenergic nerve axons and released upon depolarization of the nerve. Epinephrine together with norepinephrine is present in and released from the adrenal medulla. The ratio of epinephrine to norepinephrine present in the adrenal gland is species dependent, with the ratio in the human being approximately 80 : 20.

A major effect of exogenously administered norepinephrine is increased systolic and diastolic blood pressure, which is accompanied by reflex slowing of the heart rate. This is a result of its α_1 stimulant effects which cause vasoconstriction, with reduced blood flow in the kidneys, liver, skin, and usually skeletal muscle. Norepinephrine causes the pregnant uterus to contract and high doses release glucose from the liver and have other hormonal effects similar to those of epinephrine. It produces little stimulation of the CNS. The β -adrenergic effects of epinephrine and to a lesser extent norepinephrine include positive inotropic and chronotropic actions on the heart and bronchodilatation in the lungs.

Norepinephrine is one of the “stress hormones” and endogenously affects parts of the human brain where attention and impulsivity are controlled. Physiological changes activated by a stressful event are mediated in part by activation of a nucleus in the brain stem called the locus ceruleus, which contains the cell bodies of nearly all of the noradrenergic neurons in the brain. These neurons project bilaterally from the locus ceruleus to most areas of the CNS, including the cortex, limbic system, and spinal cord (Fig. 6.4).

Figure 6.4 Midsagittal section of a rat brain showing locations of most important groups of noradrenergic neurons and distribution of their axons and terminal buttons. (From [25a].) (See color insert.)

A decrease in noradrenergic function due to a loss of locus ceruleus neurons is seen in Parkinson's and Alzheimer's diseases [26, 27]. A marked loss of noradrenergic fibers in the hippocampal formation of individuals with Alzheimer's disease correlates with the loss of cell bodies in the locus ceruleus [28].

6.3 NEUROCHEMISTRY

Norepinephrine and epinephrine are synthesized starting with the amino acid tyrosine, which is obtained from the diet and can also be synthesized from phenylalanine. Tyrosine is converted to dihydroxyphenylalanine (DOPA) by the enzyme tyrosine hydroxylase (EC 1.14.16.2). This is the rate-limiting and first committed step in the synthesis of norepinephrine and epinephrine and [29] is tightly regulated at multiple levels [29]. Disruption of the tyrosine hydroxylase gene (knockout mice) results in midgestational lethality [30]. DOPA, in turn, is decarboxylated by L-aromatic amino acid decarboxylase to form dopamine. As the name implies, this is a relatively nonselective enzyme and decarboxylates many substrates. These first two steps in the synthesis of norepinephrine and epinephrine take place in the cytoplasm of the neuron. Dopamine is transported into storage vesicles in the nerve terminals via amine-specific transporters and is hydroxylated on the β carbon to yield norepinephrine by dopamine β -hydroxylase (EC 1.14.17.1) within the vesicles. Dopamine β -hydroxylase knockout mice die during embryogenesis [31]. In the adrenal medulla and in a few brain regions, norepinephrine is converted to epinephrine by the enzyme phenylethanolamine *N*-methyltransferase.

The major mechanism by which the effects of norepinephrine are terminated is reuptake back into the nerve terminal by a high-affinity norepinephrine transporter (NET). Norepinephrine as well as epinephrine are metabolized to inactive products. Norepinephrine is metabolized by the enzymes monoamine oxidase (MAO) and catechol-*O*-methyltransferase (COMT) to 3-methoxy-4-hydroxyphenylglycol (MHPG), which in turn is oxidized to 3-methoxy-4-hydroxymandelic acid (VMA) by sequential actions of alcohol and aldehyde dehydrogenases [32]. The major metabolite found in the blood and urine is MHPG, which is incorrectly sometimes taken to provide an index of norepinephrine metabolism in the brain [32]. The majority of the metabolism of norepinephrine and epinephrine takes place in the same cells where the amines are produced. Importantly, most of this metabolism occurs independently of exocytotic release, and only a small fraction of the metabolites is formed from circulating norepinephrine and epinephrine [32].

The monoamine oxidases (EC 1.4.3.4; MAO) comprise a family of flavin adenine dinucleotide (FAD)-dependent enzymes with two members, MAO_A and MAO_B, which are products of distinct genes and have different substrate specificity [33]. The human MAO_A and MAO_B enzymes have 527 and 520 amino acid residues, respectively, resulting from their respective genes, each consisting of 15 exons. They catalyze the oxidative deamination of a variety of amines, including the catecholamines and serotonin neurotransmitters, trace amines (e.g., phenylethylamine and tyramine), and xenobiotic amines [33]. MAO_A [34] and MAO_B [35] knockout mice have been developed. In mice lacking MAO_A, norepinephrine concentrations were increased up to twofold and the mice manifested a distinct

behavioral syndrome, including enhanced aggression in males [34]. MAO_B-deficient mice show an increased reactivity to stress [35].

6.4 NOREPINEPHRINE TRANSPORTER

6.4.1 General Characteristics of NET

The NET is a member of a large family of Na⁺/Cl⁻-dependent transporters with submicromolar potency for substrates and is synthesized as a glycoprotein [36]. Other members of this family include dopamine, serotonin, γ -aminobutyric acid (GABA), glycine, proline, and taurine transporters [36, 37]. The human NET gene is located at chromosome 16q13-21 and consists of 15 exons which encode 617 amino acids [37]. It has 12 transmembrane domains and its conformation is similar to that of other membrane-associated proteins that are responsible for ion and solute transport (Fig. 6.5). The first 5 transmembrane domains of the amino terminal have been shown to be involved primarily in general uptake mechanisms. The next 3 transmembrane domains play a key role in determining tricyclic antidepressant and cocaine binding, while the carboxyl terminal region appears to mediate substrate interaction. NET concentrates norepinephrine (NE) by coupling its transport to cotransporter ions in a proposed stoichiometry of 1 NE : 1 Na⁺ : 1 Cl⁻ with a turnover rate of one transport cycle per second [38]. *N*-Glycosylation of NET appears to be essential for transporter assembly and surface expression but not for antagonist binding affinity [39].

The NET has a major role in terminating the neurochemical signal created by norepinephrine in the synaptic cleft. Reuptake of norepinephrine by NET (uptake 1) is the primary mechanism by which the biological effects of norepinephrine in the synapse are terminated. This axonal event is an energy-requiring, saturable, sodium- and chloride-dependent process.

Reuptake of norepinephrine is competitive with a variety of naturally occurring amines and drugs. Drugs of abuse such as amphetamine and cocaine and antidepressants (e.g., desipramine, imipramine, venlafaxine, reboxetine) block the

Figure 6.5 Molecular structure of NET protein. The NET protein consists of 617 amino acids and has 12 transmembrane domains (rectangles). This conformation is similar to that of other membrane-associated proteins that are responsible for ion and solute transport. Missense polymorphisms identified in the human NET gene are identified by lines. Note that the number of circles does not represent the number of amino acid residues. (Reprinted from [37a].) (See color insert.)

TABLE 6.1 Selectivity of Various Agents for NET

Drug	Binding			Transport		
	NET	SERT	Ratio	NET	5-HT	Ratio
	K _i (nM)	K _i (nM)	(SERT/NET)	K _i (nM)	K _i (nM)	(SERT/NET)
Reboxetine ^a	1.1	129	117	8	1,070	134
Desipramine	0.63	22	35	3.5	163	47
Nortripyline	1.8	15	8.3	21	279	13.3

transport of norepinephrine. This results in an elevation of the synaptic concentrations of norepinephrine and potentiation of the activation of postsynaptic receptors [37, 40]. All of these agents have antidepressant activity and many are used clinically to treat depression [41]. The affinities of some of these agents for the NET as compared to the serotonin transporter are given in Table 6.1.

The NET is regulated during development [42] and by drugs that alter noradrenergic transmission, which causes changes in the sensitivity to endogenous catecholamines [43]. Approximately 80% of the norepinephrine released by sympathetic nerves is cleared by the NET, and the remaining percent spills over into the circulation and/or is cleared by extraneuronal tissue (uptake 2) [44]. Norepinephrine reuptake is particularly important in highly innervated tissues such as the heart.

6.4.2 Genetic Variations in Norepinephrine Transporter Gene

Several polymorphisms in the NET gene have been identified. A Taq1 restriction fragment length polymorphism was the first genetic variation identified in human NET [45]. A lack of linkage with major depression or bipolar disorder was reported, and this polymorphism has not been examined further. Alternative splicing from the human NET gene produces two variants designated *hNET C-t var1* and *hNET C-t var2* in addition to the typical *hNET* isoform. The differential characteristics of these isoforms may have functional consequences [46].

Mutations in the gene encoding the NET have been considered as a potential basis for some psychiatric illnesses. Thirteen NET DNA sequence variants have been identified in patients suffering from schizophrenia or bipolar affective disorder, although there was no evidence linking these polymorphisms to psychiatric illness [47]. The initial examination of a novel T-182C polymorphism in the promoter region of the NET gene indicated that this polymorphism was not associated with the susceptibility to major depression in a German population [48]. However, two subsequent studies by other investigators have suggested that the T-182C polymorphism might indeed be associated with major depression [49, 50].

6.5 α_1 -ADRENERGIC RECEPTORS

6.5.1 General Characteristics and Regulation of α_1 -Adrenergic Receptors

The α_1 -adrenergic receptors are single-polypeptide chains (446, 519, and 572 amino acid residues for the human α_{1A} , α_{1B} , and α_{1D} subtypes, respectively) that span the membrane seven times, with the amino terminal being extracellular and the carboxyl terminal intracellular. Thus, there are three intracellular loops and three extracellular loops. In contrast to the α_2 receptors but similar to the β receptors, the α_1 receptors have a long carboxyl terminal tail (137–179 amino acid residues) and a short third intracellular loop (68–73 amino acid residues). The amino terminal of the α_{1A} and α_{1B} subtypes have three (α_{1A}) or four (α_{1B}) consensus sites for N-linked glycosylation. The carboxyl terminal tails of all three subtypes are potentially palmitoylated, thus anchoring the tail to the membrane and forming a small fourth intracellular loop. The carboxyl terminal tails also have multiple sites of phosphorylation which are thought to be important in the desensitization, recycling, and downregulation of the receptor.

The human α_1 -adrenergic receptor gene consists of two exons and a single large intron of at least 20 kb in the region corresponding to the sixth transmembrane domain. No splice variants are known for the α_{1B} and α_{1D} subtypes. By contrast, at least 10 splice variants of human α_{1A} subtype have been reported, but only 4 produce full-length receptors. These three variants differ in the length and sequence of the C-terminal domains. Ligand binding and signal transduction do not appear to be altered by splicing of these full-length receptors. Splice variant 1 predominates in most human tissues and cell lines studied [51].

Adrenergic receptors, as well as other members of the seven-transmembrane receptor superfamily, have traditionally been thought to function as monomers, but a significant amount of recent evidence suggests that these receptors can also exist as dimers consisting of identical (homodimer) or distinct (heterodimer) subunits [52, 53]. Because most of the experimental techniques used to study dimerization cannot easily distinguish between dimers and larger oligomers, the term *dimer* is used for sake of simplicity. Dimerization of seven-transmembrane receptors may alter the functional, pharmacological, or regulatory properties of the receptor and, in some cases, may be absolutely required for receptor function. The α_{1A} adrenergic receptor splice variants produce both homo- and heterodimers [54] and α_{1B} receptors form homodimers [55]. The α_{1D} receptor has been shown to dimerize with both

TABLE 6.2 Examples of Adrenergic Drugs

	α_1 Adrenergic	α_2 Adrenergic	β Adrenergic
Agonists	Phenylephrine, methoxamine	Clonidine, brimonidine (UK14304)	Isoproterenol, terbutaline
Antagonists	Prazosin, terazosin, phentolamine	Yohimbine, RX821002, phentolamine	Propranolol, pindolol, metoprolol

α_{1B} - [56] and β_2 adrenergic [57] receptors. In both cases dimerization promotes the surface expression and functional activity of the α_{1D} receptor.

In addition to norepinephrine and epinephrine, α_1 receptors are activated by a variety of nonselective and subtype-selective agonists. Agents such as phenylephrine, methoxamine, and metaraminol are relatively selective for α_1 receptors and have little or no activity at α_2 and β receptors, except at high concentrations (Table 6.2). By contrast, they have similar affinities for the three α_1 subtypes and are thus considered to be non-subtype-selective agonists. Similarly, antagonists including prazosin, terazosin, doxazosin, and tamsulosin are relatively selective for α_1 receptors and block α_2 and β receptors only at high concentrations. These antagonists all have similar affinities for the three α_1 subtypes, although tamsulosin is considered to be slightly selective for the α_{1A} and α_{1D} subtypes as compared to the α_{1B} subtype. Several other antagonists such as phentolamine and phenoxybenzamine block both α_1 - and α_2 -adrenergic receptors with similar affinities.

Several agents have been developed that are at least 10- or 20-fold selective for the α_{1A} subtype as compared to the α_{1B} and α_{1D} subtypes [51]. However, agents that are clearly selective for either the α_{1B} or α_{1D} have not yet been developed, with the exception of BMY 7378, which is an α_{1D} -selective antagonist. The α_{1A} -selective antagonists include 5-methylurapidil, niguldipine, SNAP 5089, KMD 3213, RS 17053, and A131701 [51]. Potential α_{1A} -selective agonists include cirazoline, and A61603.

When adrenergic receptors are stimulated by an agonist, their subsequent responsiveness is decreased or blunted. This biological phenomenon is called desensitization or tachyphylaxis. Several different cellular processes, with different time courses, seem to be involved. These include modulation of receptor function (minutes), receptor internalization (sequestration and endocytosis; minutes to hours), recycling to the plasma membrane (hours), degradation (hours to days), and regulation of messenger ribonucleic acid (mRNA) levels (hours to days).

Two major types of desensitization have been identified. With homologous desensitization, reduced responsiveness is observed to the agonist that originally stimulated the receptor. In heterologous desensitization a decreased responsiveness is observed with an agent unrelated to the initial stimulus. It is generally accepted that homologous desensitization involves receptor phosphorylation by a GPCR kinase of the agonist-occupied receptor, resulting in the binding of β -arrestin [58, 59].

The α_{1B} -adrenergic receptor has been the most studied of the α_1 subtypes with respect to desensitization [59]. Agonist stimulation results in the phosphorylation of specific sites located in the carboxyl tail of the receptor (serines 404, 408, and 410) which is associated with desensitization and internalization. Direct activation of protein kinase C leads to α_{1B} receptor desensitization and internalization associated

with phosphorylation by protein kinase C (serines 394 and 400). Activation of other G_q -coupled receptors as well as G_i -coupled receptors can also induce α_{1B} receptor desensitization and involves phosphorylation by protein kinase C [59, 60]. It appears that the α_{1A} [61] and the α_{1D} [62] subtypes also undergo desensitization that involves phosphorylation, although the evidence is less complete.

Transcriptional regulation of α_1 -adrenergic receptors has been shown to occur under a variety of conditions, including hypoxia, ischemic reperfusion, agonist stimulation, cyclic adenosine monophosphate (AMP) levels and growth factors [60]. The α_{1B} gene is upregulated under hypoxic conditions in vascular smooth muscle cells, whereas the α_{1D} receptor is selectively downregulated (both mRNA and protein) by platelet-derived growth factor-BB in this same cell type. Stimulation of neonatal rat cardiomyocytes with norepinephrine leads to an increase in α_{1A} message levels, whereas α_{1B} and α_{1D} levels are reduced. Several other agents that also cause hypertrophy, including phorbol esters endothelin-1 and prostaglandin F₂, as well as aortic banding in the whole animal (creating hypertrophy through pressure overload) cause similar effects [63].

6.5.2 Signal Transduction Pathways for α_1 -Adrenergic Receptors

All three of the α_1 -adrenergic receptor subtypes activate the $G_{q/11}$ family of G proteins leading to the dissociation of the α and $\beta\gamma$ subunits and the subsequent stimulation of the enzyme phospholipase C. This enzyme hydrolyzes phosphatidylinositol in the membrane producing inositol trisphosphate (IP₃) and diacylglycerol. These molecules act as second messengers mediating intracellular Ca^{2+} release via the IP₃ receptor and activating protein kinase C. Other signaling pathways that have also been shown to be activated by α_1 receptors include Ca^{2+} influx via voltage-dependent and voltage-independent calcium channels, arachidonic acid release, and activation of phospholipase A₂, phospholipase D activation, and mitogen-activated protein kinase (MAPK) [51, 64, 65]. In general, the α_{1A} subtype appears to couple most efficiently to intracellular signaling cascades whereas the α_{1D} couples least efficiently [66]. All three subtypes activate $G_{q/11}$, but only the α_{1A} and α_{1B} subtypes couple to G_{14} , and only α_{1B} couples to G_{16} [67]. The α_{1B} receptors (but not the other two) can also couple to G_o .

In addition to regulating calcium movements and smooth muscle contraction, the α_1 -adrenergic receptors also help regulate cell proliferation through the three major subfamilies of the MAPK family [extracellular regulated kinases (ERKs), c-Jun N-terminal kinases (JNKs), and the p38 kinases]. The activation of the various MAPK members appears to be highly dependent on the particular α_1 receptor subtype(s) present and also on the particular cell line or tissue being studied [51, 65].

6.5.3 Physiological Roles for α_1 -Adrenergic Receptors

In the periphery, a primary function of α_1 -adrenergic receptors appears to be in maintaining resting vascular tone. This is due primarily to the presence of postjunctional α_1 receptors in a wide array of vascular beds in the systemic arterial circulation. By contrast, in the venous system both α_1 and α_2 receptors contribute to the vasoconstriction [64]. The question of which α_1 subtype is involved in vasoconstriction is not easy to determine because most vascular smooth muscle

tissues express mixtures of α_1 subtypes. Thus, in most cases responses to α_1 agonists are probably due to activation of more than one receptor subtype. For example, in the rat the α_{1A} and α_{1D} subtypes appear to regulate the larger vessels, whereas the α_{1B} subtype controls the small resistance vessels [64]. Recent studies with knockout mice also indicate that all subtypes play a role in the blood pressure response to α_1 agonists through their vasocontractile responses. The extent of the contribution of each of the α_1 subtypes to the contraction of vascular smooth muscle involved has not yet been completely resolved by these studies [68]. In addition, α_1 receptors may also be involved in the regulation of vascular smooth muscle growth; the α_{1B} receptor appears to induce hypertrophy of arterial smooth muscle cells, whereas the α_{1A} attenuates this growth response [64].

Selective α_{1A} -adrenergic receptor antagonists appear to have significant therapeutic advantages over non-subtype-selective α_1 antagonists in the treatment of benign prostatic hypertrophy. Although the α_{1A} subtype is the predominant α_1 subtype in human prostatic smooth muscle and does mediate contraction in this tissue, functional studies have not yet shown that this is the primary subtype mediating the beneficial response [64].

Although the predominant postjunctional adrenergic receptor type in the heart is the β -adrenergic receptor, the α_1 receptors play an important subsidiary role, particularly in increasing the force of contraction at low rates of beating. This inotropic effect appears to be mediated by both the α_{1A} and α_{1B} subtypes [69, 70]. The α_{1A} subtype also appears to be the subtype primarily responsible for the events leading to cardiac hypertrophy caused by adrenergic agents [70].

The role of the α_1 receptors in CNS function is only poorly understood. They appear to be postsynaptic, stimulatory receptors and affect many brain functions, at least in part through nonneuronal mechanisms because they are also present in glial cells [68]. The α_{1B} subtype predominates in the cortex in both the human and rat brain. Recent data suggest that the α_1 receptors are involved in locomotion and the control of motor activity as well as in cognitive functions and behaviors such as learning, memory, and fear. Interestingly, the α_{1B} subtype may enhance apoptotic neurodegeneration, which suggests that α_{1B} antagonists may have therapeutic potential in the treatment of human neurodegenerative disorders [68].

Several α_1 -adrenergic receptor polymorphisms have been noted, including a C-to-T polymorphism in the α_{1A} subtype. No linkage, however, has been found between this polymorphism and attention-deficit hyperactivity disorder, Alzheimer's disease, or the reward-dependence personality trait.

6.6 α_2 -ADRENERGIC RECEPTORS

6.6.1 General Characteristics and Regulation of α_2 -Adrenergic Receptors

The α_2 -adrenergic receptors are single-polypeptide chains (450, 450, and 461 amino acid residues for the human α_{2A} , α_{2B} , and α_{2C} subtypes, respectively) that span the membrane seven times, with the amino terminal being extracellular and the carboxyl terminal intracellular. In contrast to the α_1 and β receptors, the α_2 receptors tend to have long third intracellular loops (148–179 amino acid residues) and a short carboxyl terminal tail (20–21 amino acid residues). The amino terminal of the α_{2A} and α_{2C}

subtypes have two consensus sites for N-linked glycosylation, and the carboxyl terminal tails of all three subtypes are potentially palmitoylated, thus anchoring the tail to the membrane and forming a fourth intracellular loop. The third intracellular loops have multiple sites of phosphorylation which are thought to be important in the desensitization, recycling, and downregulation of the receptor. The α_2 -adrenergic receptor genes do not contain introns, and thus there are no splice variants.

In addition to norepinephrine and epinephrine, α_2 receptors are activated by several nonselective and subtype-selective agonists. Agents such as clonidine, guanfacine, guanabenz, and brimonidine are relatively selective for α_2 receptors and have lower affinity at α_1 and β receptors (Table 6.2). By contrast, they have similar affinities for the three α_2 subtypes and are thus considered to be non-subtype-selective agonists. Similarly, antagonists including yohimbine, idazoxan, and RX821002 are relatively selective for α_2 receptors and block α_1 and β receptors only at higher concentrations. These antagonists have similar affinities for the three α_2 subtypes. Antagonists that are at least somewhat selective for one of the α_2 subtypes include BRL44408 for the α_{2A} , prazosin and ARC-239 for the α_{2B} (note, however, that these two agents have much higher affinities for α_1 receptors), and rauwolscine for the α_{2C} subtype [71]. Ozymetazoline is a partial agonist that has a higher affinity for the α_{2A} subtype as compared to the α_{2B} and α_{2C} subtypes.

Most α_2 -adrenergic receptors also undergo desensitization and downregulation (a decrease in receptor density) following stimulation by epinephrine, norepinephrine, or other α_2 agonists, as described above for the α_1 receptors. There are, however, subtype, tissue, and species differences in the extent of desensitization [72]. Desensitization after short-term agonist exposure appears to involve G-protein-coupled receptor kinase (GRK)-dependent phosphorylation of sites in the third intracellular loop of the human α_{2A} and α_{2B} receptors. In contrast, the human α_{2C} receptor does not desensitize, although the opossum α_{2C} receptor does desensitize [73, 74]. Agonist-induced downregulation in response to long-term (~ 24 -h) epinephrine or norepinephrine exposure occurs for all three subtypes in cell lines normally expressing the receptor as well as in cell lines transfected with the receptors. The time course of downregulation varies with subtype, species, and cell type. In cell lines, it appears that an increase in the rate of receptor degradation is the mechanism for downregulation of α_{2A} and α_{2B} receptors [75]. A common polymorphism has been identified in the third intracellular loop of the α_{2B} (a deletion of three glutamate residues) resulting in a loss of short-term agonist-induced desensitization [76].

Receptor regulation appears to be important in the etiology and treatment of clinical depression. A characteristic of most antidepressant drugs is that they increase the synaptic concentration of norepinephrine (and other monoamines) by inhibiting metabolism (MAO inhibitors), blocking the high-affinity reuptake (classical tricyclic antidepressants, selective norepinephrine reuptake inhibitors) or blocking the pre-synaptic α_2 -adrenergic inhibition of neurotransmitter release (α_2 antagonists). Thus, the mechanisms of downregulation produced by these drugs are thought to be similar to those of agonist-induced downregulation. In the rat brain α_2 -adrenergic receptors are desensitized and downregulated following chronic, but not acute, administration of antidepressants [77–79]. Recent evidence from knockout mice suggests that the effects of the antidepressant imipramine are mediated by the α_{2A} receptor subtype [80]. Except for the caudate (or striatum in the rat) the predominant subtype is the α_{2A} (or α_{2D} in the rat) in nearly all brain areas [81].

During postnatal development there is an overall increase in α_2 receptor levels with great variability in pattern and timing of receptor density changes among brain regions. Three major patterns are apparent. First, in many regions receptor density increases during postnatal development, generally reaching adult levels around postnatal day 15. Second, there are regions with very high levels of receptors at birth and little or no change in density during the postnatal period. Third, in some regions α_2 -adrenergic receptors either decrease or are only transiently expressed during the course of postnatal development, including white matter regions, cerebellum, and many brain stem nuclei, suggesting specific roles for α_2 receptors during development [82].

Using agonist-stimulated [35 S]GTP γ S binding as a functional assay, it has been shown that α_2 -adrenergic receptors are coupled to G proteins throughout postnatal development [83].

6.6.2 Signal Transduction Pathways for α_2 -Adrenergic Receptors

All three of the α_2 -adrenergic receptor subtypes activate the $G_{i/o}$ family of G proteins leading to the dissociation of the α and $\beta\gamma$ subunits and a subsequent alteration (classically inhibition) in the activity of the enzyme adenylate cyclase, which lead to changes in the concentration of the second messenger cyclic AMP. In addition, the stimulation of α_2 receptors can affect several other effector systems, including the activation of K^+ channels, inhibition or activation of Ca^{2+} channels, and activation of phospholipase A_2 , phospholipase C, and Na^+/H^+ exchange [84].

The regulation of adenylate cyclase by receptors that activate the G_i family of G proteins is complex due the existence of nine differentially regulated isoforms (or isoforms), each the product of a different gene [85]. The α_i subunit inhibits the activity of isoforms 5 and 6 by acting at a site symmetrical to the G_s binding site (which stimulates enzyme activity). In addition, the released $\beta\gamma$ subunits are strong modulators of adenylate cyclase activity and can either be stimulatory (at isoforms 2, 4, and 7) or inhibitory (at isoforms 1 and 8). In fact, the $\beta\gamma$ subunit is among the most potent of all negative regulators of isoforms 1 and 8 and can markedly inhibit the enzyme activity stimulated by forskolin, G_s , and Ca^{2+} -calmodulin. This is particularly relevant to the functioning of the CNS because both the G_i proteins and cyclase isoforms 1 and 8 are highly expressed in the brain [85]. Released $\beta\gamma$ subunits stimulate the cyclase activity of isoforms 2, 4, and 7, but only when adenylate cyclase has already been activated by G_s . This synergistic activation of cyclase by receptors coupled to G_i and by receptors coupled to G_s has been termed "coincidence signaling" and may play a prominent role in the integration of the various signals received by a given neuron.

The α_2 -adrenergic activation of G_i -protein-gated K^+ channels results in membrane hyperpolarization, which in turn causes a decrease in the firing rate of excitable cells in the CNS. This effect is Ca^{2+} dependent in many but not all systems [84]. Decreased Ca^{2+} conductance mediates α_2 -adrenergic inhibition of neurotransmitter release, one of the most prominent physiological actions of α_2 receptors. This effect involves direct inhibition of N-type voltage-gated Ca^{2+} channels and can be independent of cyclic AMP and protein phosphorylation [84].

6.6.3 Physiological Roles for α_2 -Adrenergic Receptors

The α_2 -adrenergic receptors, which are found throughout the peripheral and central nervous systems, mediate a variety of effects including hypotension, sedation, and antinociception as well as a variety of behavioral effects. In addition, α_{2A} receptors on platelets mediate aggregation and stimulation of α_2 receptors in the pancreas inhibits insulin release.

Activation of α_{2A} receptors in the rostral ventrolateral medulla decreases sympathetic outflow, causing a reduction in arterial blood pressure and heart rate [86]. This mechanism is the means by which α_2 agonists such as clonidine lower blood pressure in hypertensive patients. In addition to this centrally mediated response, there is a transient hypertensive response following rapid intravenous (i.v.) injection, caused mainly by α_{2B} -adrenergic receptor-mediated vasoconstriction of vascular smooth muscle [87, 88]. The α_2 subtype mediating these effects has been determined through the use of mice lacking each of the subtypes (knockout animals). The hypotensive response to administration of α_2 agonists was abolished in α_{2A} knockout animals, demonstrating that the α_{2A} subtype plays a principal role in this response. The bradycardic response to agonist was also blunted [89]. The hypertensive response was abolished in α_{2B} knockout mice, and the hypotensive effect was immediate and accentuated. The bradycardic response in α_{2B} knockout mice was normal, and α_{2C} knockout mice showed no differences from wild-type strains in their hypertensive, hypotensive, and bradycardic effects [87, 88].

Due to the sedative effects mediated by α_{2A} -adrenergic receptors, α_2 agonists have been used as anesthetic agents in veterinary practice for the past 25 years and are now finding use in humans as adjuncts to anesthesia [90]. The sedative effects of α_2 agonists were abolished in mice lacking the α_{2A} subtype as determined by rotarod, loss of righting reflex and spontaneous locomotor activity tests [91], indicating that the α_{2A} -adrenergic receptor mediates the sedative effects of agonist administration [87, 88]. In contrast, both α_{2B} and α_{2C} knockout mice show dose-dependent sedative effects which are indistinguishable from wild-type mice. α_2 agonists appear to induce sedation by activating presynaptic autoreceptors in the locus ceruleus, reducing its spontaneous rate of firing. In addition, α_2 agonists can reduce the requirement for other anesthetic agents by as much as 90% [90]. This anesthetic-sparing effect also appears to be mediated by the α_{2A} subtype.

Another therapeutic effect mediated by the α_{2A} -adrenergic receptor is analgesia. The α_2 -adrenergic agonists have analgesic properties when given parenterally, epidurally, or intrathecally. Descending noradrenergic antinociceptive systems originating in the brain stem contribute to pain control by suppressing the spinal centripetal transmission of nociceptive impulses [90]. Once again the α_{2A} subtype appears to mediate this effect, based on studies in genetically engineered mice using the ramped hot plate, hot-water immersion, and tail-flick latency tests [87, 88]. Similar to the hypertensive, sedative, and analgesic effects, the hypothermic effect also appears to be mediated primarily by the α_{2A} subtype with a small contribution from the α_{2C} subtype. The α_{2A} -adrenergic receptor also mediates the antiepileptogenic actions of norepinephrine in the kindling model of epileptogenesis [87].

The α_{2A} -adrenergic receptor also appears to be the subtype mediating the effects of antidepressant drugs in the mouse [80]. A genetic knockout of the α_{2A} receptor makes

mice less active in the forced-swim test and insensitive to the antidepressant effects of the tricyclic drug imipramine. Thus, the α_{2A} -adrenergic receptor may play a protective role in some forms of human depression and anxiety and the antidepressant effects of imipramine and other antidepressants may be mediated in part by the α_{2A} -adrenergic receptor.

Presynaptic inhibition of norepinephrine release is a classical α_2 -adrenergic receptor function. The α_2 agonists can inhibit release of norepinephrine from nerve terminals and antagonists can enhance release. These negative-feedback effects are mediated by terminal and by somadendritic α_2 receptors [92]. There is, however, some debate as to whether this extends to endogenously released norepinephrine. Some authors question if under normal physiological conditions there is local regulation of neuronal transmitter release by autoreceptors as a result of these receptors being activated by the perineuronal concentration of previously released transmitter [93]. Initial data from knockout animals indicated that the α_{2A} subtype was the most important in mediating presynaptic α_2 -adrenergic receptor inhibition of neurotransmitter release, although a role for at least one other subtype seemed probable. Subsequent studies on the sympathetic nerves in the hearts of mice lacking one or both (double knockout) of the α_{2A} and the α_{2C} subtypes indicated that the α_{2A} receptor inhibits transmitter release at high stimulation frequencies, whereas the α_{2C} subtype regulates release at lower levels. The regulation at both high and low frequencies appears to be physiologically important [87, 88].

In comparison to the α_{2A} subtype, relatively less has been discovered about the functions of the α_{2B} and α_{2C} subtypes through knockout experiments. As noted above, the α_{2B} subtype appears to have a dominant role in eliciting the vasoconstrictor response to α_2 -adrenergic agonists, at least under some situations. The α_{2B} -adrenergic receptor has also been implicated in salt-induced hypertension and may be important in developmental processes, although the actual role it plays is currently unknown. The α_2 receptors are expressed on vascular smooth muscle cells and initiate vasoconstriction, although they have a unique distribution in the human vasculature as compared to α_1 receptors [64]. Because of their role in vascular thermoregulation, α_2 -adrenergic receptors are more active in cutaneous as compared with deep blood vessels [94]. They also have considerable activity in blood vessels of the nasal mucosa, where their activity predominates over α_1 -adrenergic receptors [95, 96]. Indeed, phenylpropanolamine (*dl*-norephedrine), once widely used as a nasal decongestant, is a preferential α_2 -adrenergic agonist [97].

The α_{2C} subtype does not appear to play a significant role in cardiovascular regulation or the other classical effects of α_2 -adrenergic receptors, with the exceptions of the hypothermic and presynaptic effects noted above. Studies with genetically modified mice suggest that the α_{2C} subtype may play a role in stress-dependent depression, in startle responses and prepulse inhibition (which may relate to schizophrenia, attention-deficit hyperactivity disorder, and posttraumatic stress disorder), in modulating motor behavior, and perhaps in memory processes [87, 88].

The α_{2C} receptor has a higher density in the striatum compared to other brain regions, but its physiological role is unknown. Recent studies with knockout mice suggest that the α_{2C} subtype regulates striatal GABA release and that the endogenous catecholamine activating the receptor may be dopamine rather than norepinephrine [98].

The α_{2C} subtype may also play a role in modulation of schizophrenia symptoms by antipsychotic drugs. Although the antipsychotic agents display rather equivalent efficacy against the positive symptoms of schizophrenia, they differ with respect to improvement of the negative symptoms such as cognitive dysfunction. These differences are potentially related to the relative affinities of the antipsychotics for the dopamine D_2 receptor and for receptors for other neurotransmitter systems. Interestingly, the affinity of clozapine, one of the so-called atypical antipsychotics, is about 12 times more potent at the α_{2C} receptor than at the dopamine D_2 receptor, suggesting that α_{2C} -adrenergic receptor blockade may contribute to the improvement of cognitive function produced by clozapine [99].

Polymorphisms have been identified in each of the α_2 -adrenergic receptor subtypes. For the α_{2A} subtype, there are two known polymorphisms in the promoter region (identified by Msp-I and Dra-I). No evidence was found for linkage of the α_{2A} gene with attention-deficit hyperactivity disorder. In addition, there is an infrequent polymorphism (lysine for asparagine at amino acid residue 252) that results in enhanced G_i coupling and a six-residue (255–260) deletion [100].

A common polymorphism has been identified in the third intracellular loop of the α_{2B} receptor, which consists of a deletion of three glutamate residues (301–303) and is a risk factor for acute coronary events but not hypertension. This deletion results in a loss of short-term agonist-induced desensitization [100].

For the α_{2C} subtype, a common polymorphism has been identified in the third intracellular loop which consists of a deletion of four amino acid residues (322–325) and results in an impaired coupling to several effectors [100]. No evidence for linkage of a dinucleotide repeat polymorphism located approximately 6 kb from the gene was found with attention-deficit hyperactivity disorder [101].

6.7 β -ADRENERGIC RECEPTORS

6.7.1 General Characteristics and Regulation of β -Adrenergic Receptors

The β -adrenergic receptors are single-polypeptide chains (477, 413, and 408 amino acid residues for the human β_1 , β_2 , and β_3 subtypes, respectively) that span the membrane seven times, with the amino terminal being extracellular and the carboxyl terminal intracellular. In contrast to the α_2 receptors but similar to the α_1 receptors, the β receptors tend to have longer carboxyl terminal tails (61–97 amino acid residues) and shorter third intracellular loops (54–80 amino acid residues). The amino terminal of the β receptors have one or two consensus sites for N-linked glycosylation, and the carboxyl terminal tails of all three subtypes are potentially palmitoylated, thus anchoring the tail to the membrane and forming a small fourth intracellular loop. The carboxyl terminal tails also have multiple sites of phosphorylation which are thought to be important in the desensitization, recycling, and downregulation of the receptor.

The β_1 - and β_2 -adrenergic receptor genes do not contain introns, and thus they have no splice variants. By contrast, the β_3 receptor has one intron, resulting in two splice variants. However, no functional differences have been found between the splice variants [12].

The β_2 -adrenergic receptors have been shown to form homodimers [102, 103] as well as heterodimers with opioid [104] and α_{1D} -adrenergic [57] receptors. These associations appear to have important functional consequences in terms of trafficking and signaling activity.

In addition to norepinephrine and epinephrine, β -adrenergic receptors are activated by a variety of nonselective and subtype-selective agonists. Isoproterenol is the prototypic non-subtype-selective β agonist which has no activity at α_1 and α_2 receptors, except at high concentrations (Table 6.2). Epinephrine is 10- to 100-fold more potent at the β_2 receptor as compared to the β_1 subtype, whereas norepinephrine is more potent than epinephrine at the β_3 subtype. Many β_2 -selective agonists have been developed for the treatment of asthma. Due to their subtype selectivity they have a lower incidence of side effects mediated by the β_1 receptor. These β_2 -selective agonists include metaproterenol, terbutaline, albuterol, salmeterol, and ritodrine. A relatively selective agonist for the β_3 receptor is BRL37344 [11].

Propranolol is the prototypic non-subtype-selective β antagonist which has equal affinities at the β_1 and β_2 subtypes and no activity at α_1 and α_2 receptors, except at high concentrations. Other nonselective β -adrenergic antagonists include nadolol, timolol, pindolol (which is actually a weak partial agonist), and carvedilol, which is also an α_1 antagonist. Propranolol, as well as other classical β antagonists, has low affinity for the β_3 subtype, which has previously been referred to as the atypical β receptor [71]. Several β_1 -selective antagonists have been developed, such as metoprolol, esmolol, acebutolol, and CGP 20712. A useful β_2 -selective antagonist is ICI 118551 [71].

The processes involved in desensitization have been extensively investigated for the β_2 -adrenergic receptor, which is the prototypic GPCR model with cells in culture. Initial uncoupling of the β_2 receptor from the G protein after agonist binding is mediated by phosphorylation of specific residues in the carboxyl tail of the receptor. The phosphorylated β_2 receptor serves as a substrate for the binding of β -arrestin, which not only uncouples the receptor from the signal transduction process but also serves as an adapter protein that mediates the binding of additional signaling proteins and entry into the internalization pathway [105, 106]. The mechanisms of β_2 -adrenergic receptor downregulation appear to involve both an increase in the rate of degradation of the receptor and a decrease in the levels of β receptor mRNA [107].

A common result of chronic but not acute antidepressant drug administration to rats is downregulation of β -adrenergic receptors and/or desensitization of β -adrenergic-stimulated adenylate cyclase. This has been observed with most classes of antidepressant drugs as well as with electroconvulsive shock [108, 109]. This downregulation is not immediate but occurs only after days to weeks of drug treatment, consistent with the therapeutic time course. Downregulation is more likely to be observed with the β_1 - as compared to the β_2 -adrenergic receptor [110].

6.7.2 Signal Transduction Pathways for β -Adrenergic Receptors

All three of the β -adrenergic receptor subtypes activate the G_s family of G proteins leading to the dissociation of the α and $\beta\gamma$ subunits and subsequent activation of the enzyme adenylate cyclase, which lead to increases in the concentration of the second messenger cyclic AMP. In addition to G proteins, β -adrenergic receptors interact with many other signaling proteins. For example, the cytoplasmic tail of the

β_2 -adrenergic receptor binds to the phosphoprotein EBP50 (ezrinradixin-moesin-binding phosphoprotein-50) through a PDZ domain and to the Na^+/H^+ exchanger regulatory factor (NHERF) also through a PDZ domain [111], whereas the β_1 -adrenergic receptor binds to CNrasGEF (cyclic AMP-dependent Ras exchange factor), which leads to Ras activation [112]. The identification and functional significance of these interactions is currently an area of intense study [111]. Following binding of agonist, the β_2 receptor is phosphorylated by β -adrenergic receptor kinase (β ARK) and the phosphorylated receptor binds β -arrestin [105, 106]. The β -arrestin serves as an adapter or scaffolding protein, which binds a variety of other proteins such as clathrin (important in the internalization of the receptor), and various signaling proteins including Src family tyrosine kinases and the ERK and JNK MAPKs [106, 111].

6.7.3 Physiological Roles for β -Adrenergic Receptors

The β -adrenergic receptors modulate a wide range of physiological responses in the intact animal, including cardiac contraction, vascular and smooth muscle tone, and carbohydrate and lipid metabolism. The β_1 subtype is considered to be the “cardiac” β receptor because these receptors predominate in the heart and in vivo stimulation of these receptors with agonists increases both force and rate of cardiac contraction. The β_2 -adrenergic receptors are also expressed in the heart and in some species influence heart rate and contractility [113]. There is considerable heterogeneity in the tissue distribution and function of β receptor subtypes in the heart. In the adult human left ventricle, the ratio of β_1 to β_2 receptors is 80 : 20, whereas in the atria the ratio decreases to 70 : 30 [114]. The β_2 -adrenergic receptor is the predominant subtype mediating peripheral vascular as well as bronchial and uterine smooth muscle relaxation. Thus, β_2 agonists are useful in the treatment of asthma and premature labor. There are also differences in β -adrenergic signaling during development, and cardiac β_2 -adrenergic receptors may play a more substantial role in mediating contractile changes in the noninnervated fetal and neonatal heart [113].

In the CNS, β_1 -adrenergic receptors are generally associated with forebrain structures such as the cerebral cortex, striatum, and hippocampus, whereas the β_2 subtype predominates in the cerebellum, as determined by radioligand binding, in situ hybridization, and immunohistochemistry [115]. There is some evidence that indicates that a significant fraction of the β -adrenergic receptors may be located on glial cells.

A decrease in norepinephrine-stimulated cyclic AMP accumulation in the cortex is observed following chronic (but not acute) treatment with a variety of typical and atypical antidepressant agents as well as for monoamine oxidase inhibitors and electroconvulsive shock. Selective serotonin reuptake inhibitors such as zimelidine and clomipramine as well as norepinephrine reuptake inhibitors reduce norepinephrine-stimulated adenylate cyclase activity. Most but not all antidepressant treatments also downregulate β -adrenergic receptor density in many brain regions. In spite of intense research, the role played by β -adrenergic receptors in depression and in the mechanism of antidepressant drugs is still not well understood [116].

Gene knockout approaches have been utilized to disrupt expression of all three β -adrenergic receptors individually as well as in various (double-knockout) combinations. The role of each of the subtypes regulating cardiovascular physiology and

metabolism has then been determined in these mice [113]. Neither the β_1 nor the β_2 subtype is required for normal cardiac development. Mice lacking the β_1 , the β_2 , or both subtypes have normal resting heart rate, blood pressure, and cardiac output, suggesting that although these β -adrenergic receptors are responsible for regulating changes in heart rate, blood pressure, and contractility during activity or stress, they are not required for maintaining normal function [113]. The β_1 -adrenergic receptor is primarily responsible for sympathetically mediated changes in heart rate during stress or exercise. In the CNS, the cortex contains mostly β_1 receptors, whereas the cerebellum has a higher density of β_2 receptors as compared to other brain regions.

The gene encoding the human β_1 -adrenergic receptor is quite polymorphic with 18 single-nucleotide polymorphisms (SNPs), 17 within the coding exon for the receptor, 7 leading to amino acid substitutions, and it has been proposed that there may be 11 different genotypes [117]. The two amino acid substitutions of most interest are glycine for serine at amino acid residue 49 and arginine for glycine at residue 389. The latter polymorphism variant shows a gain of function phenotype in that it has an enhanced coupling to G_s and an increased isoproterenol-stimulated cyclic AMP response [117]. The other consistently reported alteration is an enhanced susceptibility to agonist-promoted downregulation of the glycine-49 genotype. The current data suggest an enhanced function of those two alleles, but the magnitude of the enhancement does not appear to be sufficient to allow consistent detection [117].

A total of 13 polymorphisms in the β_2 -adrenergic receptor gene and its transcriptional regulator upstream peptide have been identified [118]. Three closely linked polymorphisms, two coding regions at amino acid positions 16 and 27 and one in the upstream peptide, are common (i.e., allele frequency >0.15) in the general white population. The glycine-16 receptor exhibits enhanced downregulation *in vitro* after agonist exposure. In contrast, arginine-16 receptors are more resistant to downregulation [118]. Although initial studies suggested a relationship between the glycine-16 polymorphism and increased risk of severe asthma and increased airway responsiveness, subsequent associations with clinical asthma, atopy, and airway responsiveness have been inconsistent [119]. Liggett [118] has proposed a dynamic model of receptor kinetics to explain the polymorphism data. Glycine-16/glycine-16 homozygous individuals are already downregulated as a result of exposure to endogenous catecholamines. Thus, the tachyphylaxis caused by recurring exogenous exposure to a β -adrenergic agonist would be more apparent in the arginine-16/arginine-16 patients because their receptors had not yet been downregulated. In this model, the initial response to albuterol in β -agonist-naïve patients would be depressed in those who are glycine-16/glycine-16 homozygous because their receptors had been endogenously downregulated to a greater extent than the receptors of patients who are arginine-16/arginine-16 [118].

The β_3 -adrenergic receptor agonists are very effective thermogenic antiobesity and antidiabetic (insulin-sensitizing) agents in rodents. Their main sites of action are white and brown adipose tissue and muscle. Although adult humans have little brown adipose tissue, β_3 receptors are expressed in human white as well as brown adipose tissue and in skeletal muscle, and they play a role in the regulation of energy balance and glucose homeostasis [120]. Early evidence for the β_3 -adrenergic receptor stemmed from the discovery that β_1 and β_2 receptor antagonists lacked potency in various gut preparations and as antagonists of β -agonist-driven lipolysis. Novel β agonists were then discovered which were more potent as stimulants of lipolysis than

of atrial contraction. These compounds were found to stimulate metabolic rate and to have antiobesity and antidiabetic activity in rodents [120]. Although β_3 is the major β subtype controlling lipolysis, it also plays a role in regulating vascular tone cardiac contractility [113].

Targeted disruption of the mouse β_3 -adrenergic receptor creates conditions that predispose the animal to the development of obesity [121]. Somewhat surprisingly, however, neither mice lacking any of the three β receptors nor mice lacking both the β_1 and β_2 subtypes (double knockout) are cold sensitive or become overtly obese. By contrast, triple-knockout mice (β_1 , β_2 and β_3 all deleted) exhibit obesity and cold intolerance [122]. Thus, β -adrenergic signaling through at least one of the subtypes is essential for the resistance to obesity and cold.

A tryptophan-64-to-arginine polymorphism has been identified in the β_3 -adrenergic receptor. The allele frequency is approximately 30% in the Japanese population, higher in Pima Indians, and lower in Caucasians [123]. Type 2 diabetic patients with this mutation showed a significantly younger onset age of diabetes and an increased tendency to obesity, hyperinsulinemia, and hypertension [123].

7.1 INTRODUCTION

Dopamine (DA) is a neurotransmitter in the central and peripheral nervous systems where it regulates numerous physiological processes. Within the central nervous system (CNS), dopamine is known to regulate emotion, reward, cognition, memory, endocrine functions, and motor control. Alterations in dopaminergic transmission are known to be involved in the etiology and/or therapy of a number of neurological and psychiatric disorders, including Parkinson’s disease, Tourette’s syndrome,

*This work was supported in part by NIMH grant R01 MH063162, awarded to J.A.S.

attention-deficit hyperactivity disorder (ADHD), schizophrenia, and substance use. One of the hallmarks of these disorders is that they are all treated with drugs that either enhance or impede dopaminergic transmission.

7.2 CHEMISTRY AND METABOLISM OF DA

Dopamine is among the most ancient of extant molecules innate to biological systems. It is a component of some plants [1–7] and is broadly distributed across the animal kingdom [8, 9]. Dopamine is a member of the general chemical class of compounds known as phenylethylamines, monoamines, and biogenic amines. The International Union of Pure and Applied Chemistry (IUPAC) and common chemical names for dopamine are 4-(2-aminoethyl)benzene-1,2-diol, 3,4-dihydroxyphenethylamine, 3-hydroxytyramine, and 2-(3,4-dihydroxyphenyl)ethylamine. Its chemical structure is comprised of a catechol ring (3,4-dihydroxyphenyl) linked by an ethyl to a primary amine: Dopamine has a catecholamine pharmacophore (Fig. 7.1). The presence of ionizable hydroxyl and amine groups at physiological pH and DA's small molecular size all contribute to its high water solubility. This restricts its distribution to the aqueous phase and prevents it from readily traversing biological lipid barriers and thus restricts its passive transport across blood–gut and blood–brain barriers. Although the mechanism by which DA is actively transported across biological barriers is not well understood, DA is a good substrate for the norepinephrine transporter [11, 12] and this transporter is localized in capillary endothelial cells at the blood–brain barrier [13]. However, the DA precursor dihydrophenylalanine (L-DOPA) is actively transported by the neutral bulky amino acid transport complex 4F2hc/LAT1 that is situated in cellular membranes comprising the blood–brain barrier, which may explain why lower plasma levels of orally administered L-DOPA are observed following a high-protein meal [14, 15].

The catechol moiety of DA makes it susceptible to oxidation. Under oxidative conditions, the catechol is converted to a highly reactive quinone (3,4-diketophenyl) which, through a series of reactions, is converted to water-insoluble conjugated diene polymers that absorb light and produce the characteristic deep brown-colored precipitates observed in solutions of oxidized dopamine. Similar reactions for its precursors tyrosine and L-DOPA are responsible for the formation of melanins and related products which serve as biological pigments and account for such biological phenomena as the browning of bananas and the tanning of skin and cuticles [7, 16, 17]. In vitro studies suggest that the generation of a reactive oxygen species, which can then lead to covalent modification of thiol-containing proteins by oxidized DA,

Figure 7.1 Chemical structure of DA. The various named moieties are delimited by the brackets. The numbering of positions around the phenyl ring is indicated.

is of potential concern for Parkinson's patients taking chronic, high doses of L-DOPA and who are in a perpetual state of neurodegeneration-induced secondary oxidative stress as this has been proposed to exacerbate degeneration [18, 19]. However, this has recently been shown not to occur to a significant extent in vivo [20, 21]. Nevertheless, the formation of certain in vitro neurotoxic dopamine metabolites, such as 3,4-dihydroxyphenylacetaldehyde (DOPAL), salsolinol, or *N*-methyl(*R*)-salsolinol [22–24], may still be a source of concern [25].

Aside from its role as a precursor of pigments, in animals, DA also serves as a signaling molecule. Dopamine is considered a neurotransmitter when it is released from neuronal synapses and acts locally on presynaptic or postsynaptic DA receptors or a neurohormone when its release is humoral, meaning that it is transported to a distant DA receptor site through blood circulation. Although both synaptic and humoral responses to DA are observed in the periphery and the CNS, within the CNS DA is predominantly a neurotransmitter. An example of a humoral response in the CNS is the tonic, pulsatile release of DA from the arcuate nucleus of the hypothalamus that regulates prolactin secretion from the anterior pituitary. A humoral-type response in the periphery is the nausea induced by high plasma levels of peripheral DA via stimulation of DA receptors in the chemoreceptor trigger zone. In order to reduce such a side effect, L-DOPA is coadministered with peripheral inhibitors of the enzyme aromatic amino acid decarboxylase (AADC), such as carbidopa, which prevent the peripheral conversion of L-DOPA to DA.

Dopamine is a derivative of the aromatic amino acids phenylalanine and tyrosine and a precursor of the neurotransmitters norepinephrine and epinephrine. The anabolic and catabolic pathways for DA, as well as agents that block the enzymes that perform these conversions, are shown in Figure 7.2. Tyrosine hydroxylase is the rate-limiting enzyme in the biosynthesis of DA, and consequently, in situ intracellular localization of this enzyme is a popular marker for dopaminergic (and noradrenergic) cells. Due to its key role in DA anabolism, tyrosine hydroxylase is under heavy regulation at both the transcriptional and posttranslational levels [26–28]. Only one protein isoform of tyrosine hydroxylase is present in rats, while, due to differential splicing, two are present in nonhuman primates and four in humans [29, 30]. L-DOPA is converted to dopamine by AADCs associated with biogenic amine-containing neurons [31]. The ability of striatal serotonergic neurons and glia to convert L-DOPA to dopamine may explain why L-DOPA continues to be effective, albeit to a lesser extent, in advanced stages of Parkinson's disease when fewer dopaminergic neurons are remaining in the substantia nigra [32–34]. Once formed, DA can be converted by the enzyme dopamine- β -hydroxylase, which is present in noradrenergic neurons, or it can undergo catabolism or be taken back up following release. The two most reliable measures of DA turnover are 3,4-dihydroxyphenyl acetic acid (DOPAC)–DA and homovanillic acid (HVA)–DA ratios. HVA–DA ratios in cerebrospinal fluid (CSF), in particular, serve as an accurate measure of brain dopaminergic activity. In contrast to phase I catabolism, there are notable species and cell-type differences in the phase II catabolism of DA. For example, in rats, the major excreted metabolites are glucuronidated, while in humans they are sulfonated [35–37]. Differences in phase II metabolism of DA are also observed in cell lines derived from different tissues [38].

Drugs that regulate dopaminergic metabolism play a central role in the therapeutic management of diseases and disorders. For example, inhibitors of the catabolic enzyme monoamine oxidase (MAO) B extend the actions of DA by slowing

Figure 7.2 Metabolic pathways for DA. The names and abbreviations for the various chemical species are indicated in bold face. The enzymes responsible for the different conversion steps are indicated in italic and their corresponding inhibitors are indicated in capital text.

its degradation and therefore are sometimes used as treatments for disorders characterized by an direct or indirect hypodopaminergic state, like Parkinson's disease and ADHD, respectively. MAO_B-selective inhibitors like selegiline are effective in preventing 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) neurotoxicity, because they block the enzymatic conversion of protoxin MPTP to its toxic metabolite 1-methyl-4-phenylpyridine (MPP⁺) [39]. Although the distinctions are not absolute, MAO_B is generally associated with the metabolism of DA and tyramine, while MAO_A is primarily responsible for norepinephrine and serotonin metabolism. Older generation inhibitors of MAO carry a risk for pressor amine-induced hypertensive crisis or, when taken in conjunction with inhibitors of serotonin reuptake, serotonin syndrome, because many are irreversible inhibitors and most are only sparingly selective for the MAO_B versus the MAO_A subtypes. New MAO inhibitors that are reversible and highly selective for the A or B isoforms are becoming available (e.g., moclobemide and lazabemide, respectively) and should prove to be much safer alternatives. Catechol-*O*-methyl transferase (COMT) inhibitors are commonly coadministered to those receiving L-DOPA to counter the observed upregulation of this enzyme that results from chronic treatment. This prevents the peripheral conversion of L-DOPA to its 3-methoxy derivative that competes for active transport but that cannot then be converted to DA once inside the brain.

7.3 HISTORICAL CLASSIFICATION AND MOLECULAR PROPERTIES OF DA RECEPTORS

Dopamine is known to exert its actions through the binding and activation of specific cell surface receptors which are members of the G-protein-coupled receptor (GPCR) super gene family. Before it was established that multiple subtypes of DA receptors exist, the stimulatory effect of dopamine on adenylyl cyclase activity in the neostriatum was demonstrated [40]. Subsequent testing of dopaminergic agonists revealed that some promoted inhibition rather than stimulation of adenylyl cyclase in the striatum [41]. This discrepancy led to the classification of D₁ receptors as those which stimulate adenylyl cyclase activity and raise intracellular levels of cyclic adenosine monophosphate (cAMP) and D₂ receptors as those which inhibit adenylyl cyclase activity (reviewed in [42]). In addition to regulating adenylyl cyclase, many other intracellular effects have now been ascribed to DA receptor stimulation ([43]; and see also Section 7.4).

Through the application of molecular biological techniques, we now know that there are D₁ and D₂ *subfamilies* of receptors rather than singular receptor subtypes. The D₁ DA receptor subfamily includes the “classical” D₁ (also initially called the D_{1A}) receptor, as well as the D₅ (also initially called the D_{1B}) receptor. The D₅ receptor differs from the D₁ receptor in primary amino acid sequence and anatomical distribution but binds D₁ receptor-selective agonists and antagonists with similar affinity. The D₂ receptor subfamily includes the classical D₂ receptor, which is found in a short and long isoform (D_{2S} and D_{2L}), and also the D₃ and D₄ receptors. These D₂-like receptors exhibit a variety of pharmacological, structural, and in some cases functional similarities.

7.3.1 The D₁ Receptor Subfamily

Early molecular cloning work led to the discovery that there are actually two distinct DA receptor subtypes which are coupled to the stimulation of adenylyl cyclase. The first of these, termed the D₁ receptor, was independently cloned by four separate groups using either the polymerase chain reaction with degenerate primers derived from previously cloned GPCR sequences or homology screening with a D₂ receptor probe [44–47]. These methods enabled the isolation of complementary deoxyribonucleic acids (cDNAs) or genes from either human or rat DNA libraries. Both the rat and human D₁ receptor genes encode a 446-amino-acid protein (see Fig. 7.3). Overall, the rat and human receptors are 91% homologous at the amino acid level.

The structure of the D₁ receptor deduced by hydropathy analysis is consistent with that of other GPCRs, with seven hydrophobic domains predicted to traverse the plasma membrane. The amino acids in these domains are thought to be in the α -helical configuration. Predicted asparagine-linked glycosylation sites are found on the amino terminal domain and the second extracellular loop. The D₁ receptor has a relatively small third cytoplasmic loop, similar to other biogenic amine receptors which are coupled to the stimulatory guanyl nucleotide binding protein Gs [48, 49]. In the third cytoplasmic loop are found several serine and threonine residues as well as a consensus recognition sequence for the cAMP-dependent protein kinase, which are potential sites of phosphorylation. Other sites of postranslational modification include a cysteine residue in the carboxyl terminal domain, which is palmitoylated,

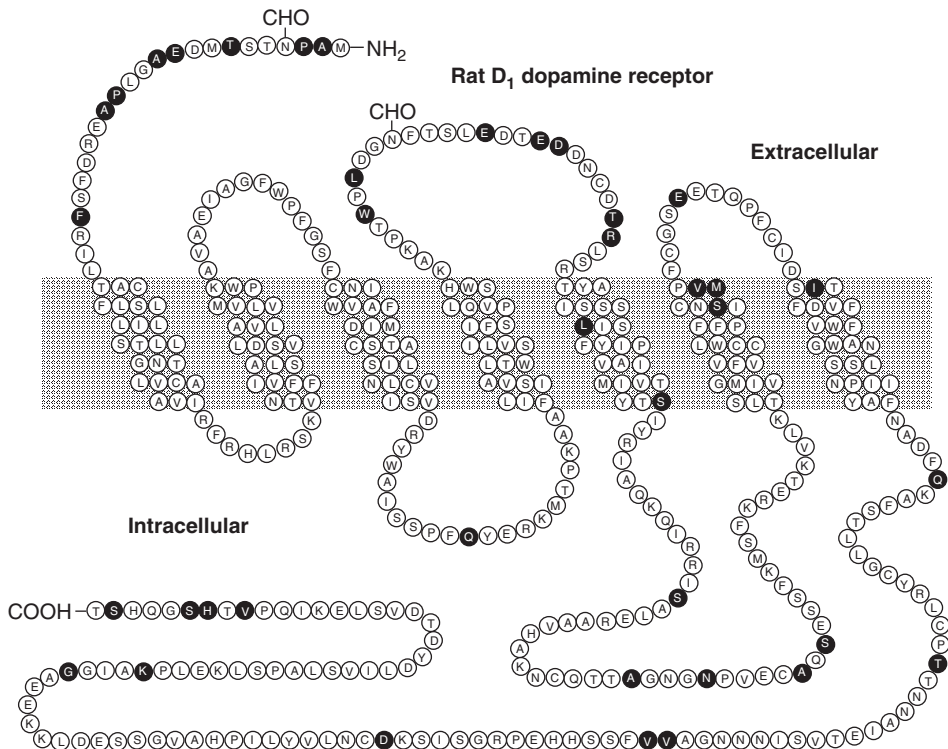

Figure 7.3 Membrane topography of rat D₁ DA receptor. Membrane-spanning domains are defined on the basis of hydropathy analysis. CHO: *N*-linked glycosylation sites. Solid residues indicate differences with the human receptor sequence.

and numerous serine and threonine residues also in the carboxyl terminus which serve as sites of G-protein-coupled receptor kinase (GRK)-mediated phosphorylation [50].

The human D₁ receptor gene has been mapped to chromosome 5 [46], and the 5' flanking regions of the rat and human D₁ genes have been studied [51–53]. While the coding region is intronless, the rat and human D₁ receptor genes contain a small intron in the 5' noncoding region. The promoter does not contain a TATA box or CAAT box; however, several SP1, AP1, and AP2 sequences have been identified. Also found in the promoter region is a cAMP responsive element recognition sequence.

Localization of the D₁ receptor messenger ribonucleic acid (mRNA) expression has been mapped using Northern analysis and in situ hybridization (for a review, see [54]). Expression of D₁ receptor mRNA is highest in the caudate putamen, nucleus accumbens, and olfactory tubercle. Lower levels of expression are found in the basolateral amygdala, cerebral cortex, septum, thalamus, and hypothalamus. D₁ receptor binding activity measured with the antagonist [³H]SCH-23990 is closely matched with mRNA expression in the striatum, amygdala, nucleus accumbens, and suprachiasmatic nucleus, consistent with the belief that D₁ receptors are localized largely on neuronal cell bodies rather than nerve terminals in these nuclei [55].

The second D₁-like receptor, referred to as the D₅ receptor, was isolated from human genomic libraries in 1991 [56–58]. The human D₅ receptor, which contains 477 residues, shares 50 and 80% homology with the human D₁ receptor in their coding regions and transmembrane-spanning domains, respectively. The rat homolog of this receptor was initially termed the D_{1B} receptor, consistent with classification of the receptor in the D₁-like subfamily [59, 60]. The rat D_{1B} receptor encodes a 475-amino-acid protein which is 83% homologous with its human homolog, the D₅ receptor. Like the D₁ receptor, the D_{1B} and D₅ receptors have asparagine-linked glycosylation sites in the amino terminus and the second extracellular loop, a small third cytoplasmic loop with putative phosphorylation sites, and a cysteine residue in the carboxyl terminus. The coding region in these genes also lacks introns [56–58] as in the D₁ receptor gene.

In the human genome, two pseudogenes related to the D₅ receptor have been isolated and termed *D5ψ1* and *D5ψ2* [56, 58, 61]. The nucleotide sequences of these pseudogenes are 95% conserved with the human D₅ sequence. Expression of functional proteins from the sequences does not occur due to insertions and deletions which encode termination codons. The *D5ψ1* gene has been shown to be transcriptionally active, and the resulting *D5ψ1* mRNA is recognized by most probes used for in situ hybridization analysis of the D₅ receptor [62]. The *D5ψ2* appears to be transcriptionally active as well [63]. In the human, the D₅ receptor gene and the pseudogenes are not found on the same locus, as the D₅ receptor gene has been mapped to chromosome 4 and the *D5ψ1* and *D5ψ2* to chromosomes 1 and 2, respectively [61, 64, 65].

Both the rat and human D₅ receptor homologs stimulate adenylyl cyclase activity and bind D₁-selective ligands with similar affinities as the D₁ receptor. While no ligands exhibit substantial preference for either subtype, DA binds with a 5- to 10-fold higher affinity to the D₅ receptor than to the D₁ receptor [56–60]. The reason for this high degree of pharmacological similarity is probably due to high structural homology that these receptors show in the transmembrane-spanning/ligand binding domains. It remains a formidable task for medicinal chemists to design drugs that are significantly selective for either of these D₁-like receptors. Another notable distinction between the two D₁-like receptors is that the D₅ receptor has been suggested to be constitutively active when expressed in HEK-293 cells [66].

The localization pattern of D₅ receptor mRNA differs significantly from that of the D₁ receptor. Interestingly, D₅ receptor mRNA expression has not been observed in the striatum using Northern or in situ hybridization analysis [57, 58, 60], suggesting that this receptor may not play as large a role in motor control as the D₁ receptor. In the rat, regions where D₅ receptor mRNA expression is observed to be high include the olfactory tubercles, hippocampus, hypothalamus, and mamillary bodies. Localization of D₅ receptor binding by in vitro autoradiography is currently not possible due to the absence of a highly selective D₅ receptor radioligand.

7.3.2 The D₂ Receptor Subfamily

As the D₂ receptor was the first DA receptor to be cloned, its isolation was dependent on homology to a similar GPCR. Low-stringency screening of a rat genomic library with a β₂-adrenergic receptor probe yielded homologous DNA fragments which were

subsequently used to isolate cDNA clones from a rat brain library. One of these clones was found to be the D₂ receptor [67]. The human D₂ receptor homolog was subsequently cloned and found to be 96% identical with the rat receptor with one amino acid deletion [68–71]. The human D₂ receptor gene has been mapped to chromosome 11 [72]. Structurally, the D₂ receptor contains a large third cytoplasmic loop, a short carboxyl terminal tail and three asparagine-linked glycosylation sites in the amino terminal region (see Fig. 7.4). The main structural difference between the D₂ and the D₁ receptor subfamilies is that the D₂-like receptors have large third cytoplasmic loops and short carboxyl termini, structural motifs that are characteristic of G_{i/o}-coupled receptors.

When transfected into mammalian cells, cloned D₂ receptors have been shown to activate a variety of signal transduction pathways ([43]; see also Section 7.4). In addition to adenylyl cyclase inhibition [73], these include stimulation of arachidonic acid release [74, 75], phosphatidylinositol hydrolysis and mobilization of calcium [76], regulation of K⁺ channels [77–79], and suppression of prolactin release [80]. With a few exceptions, these effects are similar to those observed in endogenous D₂ receptor-expressing tissues. The signaling properties of D₂-like receptors are discussed in detail below.

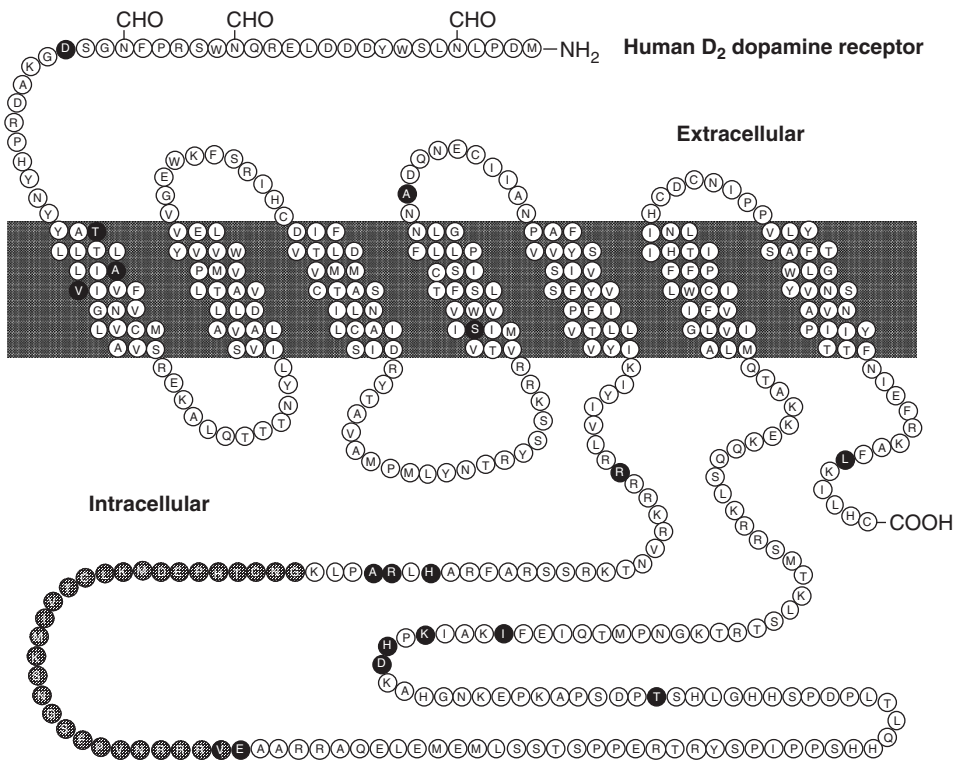

Figure 7.4 Membrane topography of human D₂ DA receptor. Membrane-spanning regions are defined on the basis of hydrophathy analysis. The hatched circles indicate the alternatively spliced exon of the D₂ receptor. The solid circles indicate differences with the rat receptor sequence. CHO: N-linked glycosylation sites.

Many studies have been conducted to investigate the localization of D₂ receptor mRNA in the brain [81–86]. The D₂ receptor mRNA distribution correlates well with previous information on D₂ receptor distribution generated using receptor binding and autoradiography methods. The areas of highest expression in the brain include the caudate putamen, nucleus accumbens, and olfactory tubercle. Receptor mRNA is also found in dopaminergic cell bodies within the substantia nigra pars compacta and ventral tegmental areas, suggesting an additional presynaptic role for the D₂ receptor. Cellular localization of the D₂ receptor mRNA has also been investigated in the striatum, where about 50–75% of the medium-sized cells appear to express receptor mRNA [87–89]. Recent evidence indicates that most of the cells which express the D₂ receptor mRNA in high abundance are enkephalinergic neurons [54, 87]. D₂ receptor mRNA has also been observed in large-diameter cells in the striatum, the majority of which appear to be cholinergic interneurons [54].

The D₂ receptor RNA is known to undergo alternative splicing, as two isoforms with different-sized coding regions have been isolated [59, 68–70, 90–92]. The D₂ long (D_{2L}) receptor contains a 29-amino-acid sequence which is absent from the D₂ short (D_{2S}) receptor. This sequence is encoded by one of the eight exons of the D₂ receptor gene [68, 70, 72, 93–95]. Both isoforms are found in human, rat, bovine, and murine tissue. They share similar pharmacological profiles and functional attributes, although they may act via different G proteins to mediate adenylyl cyclase inhibition [68, 96] and to regulate potassium channels [77–79]. The function of the 29-amino-acid sequence may also be to target the receptor isoforms to different regulatory pathways. This hypothesis stems from observations of differential effects of agonist pretreatment on the different receptor isoforms. Zhang *et al.* [97] found that agonist pretreatment of D_{2L} receptor-expressing cells resulted in upregulation of receptor expression whereas a similar treatment of D_{2S} receptor-expressing cells resulted in receptor downregulation.

The second receptor in the D₂-like subfamily to be identified was the D₃ receptor. Cloned in 1990 [98], the D₃ receptor shares 52% overall homology and 75% transmembrane homology with the D₂ receptor. The rat D₃ receptor is 446 amino acids long and contains asparagine-linked glycosylation sites in the amino terminus, a cAMP-dependent protein kinase recognition sequence in the third cytoplasmic loop, and a cysteine residue in the carboxyl terminal domain. The human D₃ receptor gene, which encodes a 400-amino-acid protein, has been cloned and mapped to chromosome 3 [99, 100]. The pharmacological profile of the D₃ receptor is similar to that of the D₂ receptor [98, 101–103].

The D₃ receptor is the only cloned DA receptor which is guanine nucleotide insensitive and relatively ineffective in regulating adenylyl cyclase activity (however, see below). However, regulation of DA release [104, 105], stimulation of neurite extension and branching [106], and activation of *c-fos* and mitogenesis [107] have all been identified as D₃ receptor-mediated events. These effects may be mediated by a second-messenger system that has yet to be elucidated. Seabrook *et al.* [108] have also shown that the D₃ receptor can depress Ca²⁺ currents in transfected NG108-15 cells. Similarly, Liu *et al.* [79], also working with NG108-15 cells, have found that the D₃ receptor can directly couple to the modulation of K⁺ currents.

In brain, D₃ receptor mRNA localization is greater in hypothalamic and limbic nuclei such as the olfactory tubercle, islands of Calleja, hippocampus, nucleus accumbens, and bed nucleus of the stria terminalis than in the basal ganglia [54,

109]. Minimal expression is observed in the caudate and putamen. D₃ receptor protein has been difficult to investigate due to the limited ligand specificity between D₂ and D₃ receptors. Use of [¹²⁵I]iodosulpiride in the presence of domperidone to reduce D₂ receptor labeling by autoradiography reveals the highest levels of D₃ binding in the islands of Calleja and the nucleus accumbens [110].

The D₃ receptor gene contains several introns and alternative splicing has been observed to produce nonfunctional variants [111, 112]. A functional variant has been identified in mice which lacks a 63-bp sequence in the third cytoplasmic loop [113]; also see Section 7.6).

The last D₂-like receptor to be identified was the D₄ receptor. Cloning and expression of this receptor was accomplished in several stages [114]. A partial-length human D₄ receptor cDNA was isolated by homology screening of a neuroblastoma cell library with a D₂ receptor probe. With this fragment used as a probe, a clone was isolated from a human genomic library which contained the coding sequence of the D₄ receptor. A full-length, correctly spliced D₄ receptor cDNA clone was subsequently isolated from a library constructed from COS cells which had been transfected with the D₄ receptor genomic DNA. The human D₄ receptor is 387 amino acids long (however, see below) and shares 41 and 56% homology with the D₂ receptor coding and transmembrane regions, respectively. Its large third cytoplasmic loop contains a cAMP-dependent protein kinase recognition site and its amino terminus contains one asparagine-linked glycosylation site.

The gene encoding the D₄ receptor, located on chromosome 11 [115], has been shown to be polymorphic [116]. A 48-bp sequence encoding 16 amino acids in the third cytoplasmic loop is repeated from two to nine times, with four repeats occurring most frequently in the population. The pharmacological profiles of D₄ receptors with varying repeat lengths appear to be similar [117]. The potential significance of this polymorphism is discussed in Section 7.6.

The binding properties of the D₄ receptor closely resemble those of the D₂ receptor [105, 114, 117–119]. As with D₂ receptors, agonist binding to D₄ receptor is guanine nucleotide sensitive. D₄ receptors are coupled to inhibition of adenylyl cyclase when transfected into a variety of mammalian cell lines [119]. In the MES23.5 neuroblastoma cell line, D₄ receptors have been shown to reduce potassium influx [120].

In rodents, the highest expression of D₄ receptor mRNA is found in the heart [118]. In rodent brain, expression is about 10-fold lower than in heart, with the highest levels observed in the frontal cortex, amygdala, olfactory bulb, and hypothalamus [114]. Very low levels of expression are detected in the olfactory tubercles and striatum.

7.4 DA RECEPTORS AS SIGNAL TRANSDUCERS

Dopamine transmits signals across cellular membranes by interacting with membrane-bound signal-transducing receptors that induce changes in the level of intracellular second messengers. Like other rhodopsin like class A GPCRs, DA receptors couple to intracellular guanosine triphosphate (GTP)-sensitive heterotrimeric G-protein complexes, although D₃ receptors may be an exception to this (see Section 7.5). The G-protein subtype coupling preference of the receptor determines

TABLE 7.1 Typical G_α Protein Coupling Preferences for Dopamine Receptors

Subfamily	Subtype	G_s	$G_i/G_o/G_z$	G_q	G_t	Comments
D ₁ -like	D ₁	+				↑ cAMP
	D ₅	+				↑ cAMP
D ₂ -like	D ₂		+			↓ cAMP
				+		↑ IP ₃
	D ₃		+			↑ Mitogenesis
			+			↑ Mitogenesis
			+		+	↓ cAMP
	D ₄		+			↑ Mitogenesis

Abbreviations: cAMP = cyclic adenosine monophosphate, IP₃ = 1,4,5-inositol triphosphate.

^aThe subscript designations indicate the G_α protein subfamily.

the type of intracellular second-messenger response. This selectivity of G-protein coupling is controlled primarily by the subtype of the α subunit (Table 7.1) and is secondarily modulated by the subtype of β and γ subunits. However, promiscuous coupling can occur when the levels of expressed G protein or receptor are very high, which suggests that the coupling preferences are by no means absolute. In general, though, the levels of receptors under physiological conditions are low enough to permit selective coupling by the different receptor subtypes. However, it is becoming apparent that heterooligomerization of DA receptors with other non-DA GPCRs can dramatically affect G-protein coupling preferences. For instance, D₂ receptors are known to prefer to couple with $G_{i/o}$ over G_s , but when coexpressed with cannabinoid CB1 receptors, this D₂ receptor-mediated coupling preference is reversed [121]. Although the strength of coupling to G-protein subfamilies and subtypes (isoforms) is known to vary among the DA receptor subtypes, the extent of intracellular signaling can depend in large part upon the presence of the appropriate isoforms of the enzymes activated by the G proteins. For example, D₃ receptor stimulation only leads to a robust increase in cAMP when the adenylyl cyclase isoform V is present [122]. The presence or absence of other receptors or specific enzyme isoforms has major implications for the development of tissue- or cell-specific drug responses.

Notwithstanding the above caveats, the canonical wisdom is that both of the D₁-like DA receptors prefer to couple to G_{α_s} proteins which stimulate the enzyme adenylyl cyclase, while all the D₂-like DA receptors couple to $G_{\alpha_{i/o}}$ proteins that inhibit this enzyme and the pertussis toxin-insensitive G_{α_z} [123]. D₂, D₃, and D₄ receptors have been shown to induce mitogenesis in serum-sensitive cell lines via a G-protein-dependent mechanism [107, 124–130]. D₂ receptors have also been shown to couple to G_{α_q} , and thereby stimulate the enzyme phospholipase C [131]. Remarkably, the D₄ receptor is among the growing number of known nonopsin receptors that couple to transducin (G_{α_t}) [132–134], which is in line with the localization of D₄ receptors in the retina [135, 136].

The GPCR cycle begins when an agonist binds to the receptor and converts it from the inactive low-affinity state to the active high-affinity state (Fig. 7.5). This induces a conformational change in the receptor that allows the inactive form of the heterotrimer G-protein complex to bind. This in turn promotes the exchange of guanosine diphosphate (GDP) for GTP from the α subunit of the G-protein in the presence of

Figure 7.5 Schematic showing critical components of signaling cycle for heterotrimeric GPCRs. (See color insert.)

magnesium ions and activates the G-protein complex. The activated GTP-bound α subunit of the G-protein complex undergoes a conformational change, which promotes the dissociation of its G-protein β and γ subunits as well as its own dissociation from the receptor. Once the receptor is no longer bound by G protein, it converts back to the low-affinity state, which promotes the dissociation of agonist. In some cases the free β and γ subunits may associate with ion channels or other proteins and modulate their activity. The activated GTP-bound α subunit associates with effector enzymes and either potentiates or inhibits their activity until the bound GTP is autohydrolyzed to GDP by the G protein. This results in a change in the conformation of the inactivated GDP-bound α subunit, which favors dissociation from the enzyme and reassociation with its β and γ subunits, and the cycle begins anew.

7.5 MOLECULAR PHARMACOLOGY OF DA RECEPTORS: STRUCTURE–AFFINITY AND STRUCTURE–ACTIVITY RELATIONSHIPS

Structure–affinity and structure–activity relationship studies coupled with molecular modeling have revealed that three major physicochemical forces influence the interactions of DA with DA receptors (see review in [137]). The primary amine portion of

DA is protonated when bound to the binding site crevice, which allows it to form a high-energy reinforced ionic bond with a negatively charged and conserved aspartic acid (3.32, for an explanation of the universal naming system for the position of amino acids within GPCRs see [138]) present in the receptor [139, 140]. In general, the catechol hydroxyls of DA form hydrogen bonds to one of the conserved serines (S5.42) and, to a lesser extent, with one of the other two adjacent serines (S5.43 or S5.46) in the receptor. While none of these three serines are essential for D₁ or D₂ DA receptor activation by agonists [141–143], at least two (any two) serines are essential for the coupling of the D₂ receptor with G proteins and consequently essential for DA activation of the D₂ dopamine receptor [143]. Although β -phenylethylamine, which is a DA derivative lacking both hydroxyl groups, can still bind to both a high- and low-affinity state of the receptor [144] and by extension should be able to activate it, its affinity as well as the affinities for *meta*- and *para*-tryamine is greatly reduced [143, 145]. Thus, it appears that serines at positions 5.42, 5.43, and 5.46 serve to increase the binding affinity of DA and to anchor it in the binding site crevice, which would orient its aromatic ring such that it sterically clashes with a conserved residue in the transmembrane TM6 aromatic cluster (possibly 6.51 or 6.52). By analogy with other GPCRs, such a clash is believed to result in conformational changes in the receptor that are ultimately responsible for its activation [146]. Accordingly, many DA agonists have structural features similar to DA and interact with similar microdomains. An exception to this is quinpirole, which apparently does not interact with the conserved serine microdomain in TM5 of D₂ or D₃ receptors [142, 145, 147, 148]. A few rigid, fused heterocyclic agonists are subfamily selective. For example, SKF38393 and dihydrexidine are D₁-like selective, and (–)-quinpirole, apomorphine, propylnorapomorphine, 2-amino-5,6-dihydroxy-1,2,3,4-tetrahydronaphthalene (5,6-ADTN), 6,7-ADTN, and 7-hydroxy-2-(*N,N*-di-*n*-propylamino)tetralin (7-OH-DPAT) are D₂-like selective. Dopamine receptor antagonists (and inverse agonists) have more divergent structures but still invariably incorporate a protonatable amine pharmacophore (see, e.g., [10]). The binding of some inverse agonists and antagonists, like butyrophenones and substituted benzamides, appears to depend upon conserved aromatics in TM6 (6.51 or 6.52) of the receptor [149, 150]). However, the manner in which antagonists and inverse agonists interact with the aromatic residue at position 6.52 must differ from the agonists, because antagonists do not activate the receptor. By definition, allosteric modulators of DA receptors interact at a site distinct from the orthosteric site, that is the site where DA binds (for a recent exhaustive review of allosteric modulators of DA receptors see [151]).

Although one or more of the three conserved microdomains are important for ligand binding, they cannot fully account for the binding of receptor subtype-selective ligands, because, as expected, selective ligands tend to take advantage of additional nonconserved receptor subtype-specific amino acids. For example, most 1,4-disubstituted aromatic piperidines/piperazines (1,4-DAPs) with extreme selectivity for the D₄ DA receptor interact favorably with an aromatic microdomain that spans the interface of the second and third transmembrane (TM2/TM3) domains of the D₄ receptor [152, 153]. Other DA receptors, such as the D₂ receptor, also have aromatic residues in the TM2/TM3 microdomain, but their placement within this microdomain is different from that of the D₄ receptor (V2.61 and F3.28 in D₂ and F2.61 and L3.28 in D₄). This may explain why the majority of D₄-selective drugs are 1,4-DAPs with related substructural features [154]; however, it does not explain why

they have a range of functional properties [152]. A couple of highly D_4 -selective 1,4-DAPs (PNU101,387G and R010-4548), with uniquely positioned electronegative substructures, have moderate interactions with only one portion of this TM2/TM3 microdomain and thus must take advantage of additional unique microdomains on the D_4 receptor or their unique structural features are differentially exploited among the receptor subtypes [152]. Furthermore, D_2 -selective 1,4-DAPs, such as methylspiperone and aripiprazole, possess unique substructural features of their own and do not have major interactions with any portion of the TM2/TM3 microdomain [153, 155]. A conserved aromatic microdomain in TM6 (residues F6.51, F6.52, and H6.55) has been implicated in the high-affinity binding of substituted benzamides, like sulpride, or butyrophenones, like methylspiperone [150], although it is unclear whether in the case of residues F6.51 and F6.52 this is a direct effect on ligand binding or a more global effect on protein structure. How molecular recognition is achieved for other much less subtype-selective chemical classes of atypical antipsychotics, including the benzapines (e.g., clozapine, olanzapine, quetiapine, loxapine) and benzazolines (e.g., risperidone, ziprasidone), remains to be elucidated [137].

7.6 SPLICE VARIANTS, SNPS, AND OTHER POLYMORPHISMS WITH FUNCTIONAL CONSEQUENCES

As discussed above, five genotypically distinct DA receptors have been cloned from humans and the corresponding homologs are present in monkeys, rats, and mice. To date alternative splice variants have been identified for D_2 and D_3 DA receptors. Both a short (D_{2S}) isoform and a long (D_{2L}) isoform, which contain a 29-amino-acid insertion in the third intracellular loop (ICL3), have been identified in humans, rats, and mice (see Section 7.3), although in mice the long isoform predominates [94]. In *Caenorhabditis elegans* both a long and a short ICL3 splice variant of a D_2 DA receptor ortholog have been identified [156], while in *Drosophila* eight D_2 receptor orthologs have been identified and each is due to alternative splicing in ICL3 [157]. However, such alternative splicing apparently does not occur in *Xenopus*, rather two distinct D_2 genes are present [158].

Although there are no large differences in the affinity for DA or other dopaminergic drugs for the D_{2S} and D_{2L} variants, only the D_{2L} isoform couples to $G\alpha_{i2}$ [159]. Furthermore, D_{2L} , but not D_{2S} , interacts with heart-type fatty acid binding protein [160] and activates NF-kappaB in a calcineurin-dependent manner [161]. The presence or absence of the 29-amino-acid insert in the D_2 receptor is also important for trafficking of the D_2 receptor, because the D_{2S} isoform resides predominantly in the plasma membrane while the D_{2L} receptor is primarily retained in the endoplasmic reticulum [162] or resides in a perinuclear location around Golgi [160]. In addition, the D_{2S} receptor has a somatodendritic or presynaptic localization where it serves as an autoreceptor, while the D_{2L} receptor has a postsynaptic localization [163, 164]. Recently, a third isoform that is two amino acids longer than the D_{2L} isoform has been identified in humans, and remarkably its affinity is reported to be considerably higher than the other D_2 splice variants [165]. Both ethanol and estradiol modulate alternative splicing of the D_2 receptor in primary pituitary cultures, which results in a relative increase of the levels of D_{2L} with a concomitant decrease in the levels of D_{2S} [166, 167].

Similar to the D₂ DA receptor, a splice variant of the mouse D₃ DA receptor has been reported that results in a shortened ICL3 (21 amino acids less) [168]. In contrast, a splice variant of the D₃ receptor has also been identified in rat brain, which results in a 28-amino-acid elongation of the first intracellular loop (ICL1) [169]. A variety of splice variants have been reported that result in an array of nonfunctional truncated D₃ receptors that encompass transmembrane-spanning domains II, III (D₃ *TM4-del*), or all seven (D₃*nf*) but lack a carboxy terminus tail [112, 170, 171]. The *D3nf* variant alone has no demonstrable functional properties and does not bind dopaminergic ligands. However, *D3nf* reduces apparent receptor density (B_{\max}), as assessed by radioligand binding, when it is coexpressed with the full-length D₃ receptor [172] and it prevents trafficking of the full-length D₃ receptor to the plasma membrane [173]. This may have physiological consequences as *D3nf* is expressed in human brain [171] and it is upregulated in the brains of chronic schizophrenics [174]. Recently, it has been shown that the functional properties and the binding of ligands to the *D3nf* truncation variant can be rescued by coexpression of the carboxy terminal tail of the D₃ receptor [175].

Many single-nucleotide polymorphisms (SNPs) have been reported in both coding and noncoding regions of DA receptors, which is not surprising given that a survey of SNPs in a panel of eight different human GPCRs reveals a frequency of one polymorphism per 584 bp [176] and that DA receptors average ~ 1300 bp in length. Despite the expected high frequency of SNPs in DA receptors, thus far only one has been reported that results in a change in the coding sequence that leads to dramatic functional consequences. Specifically, a case study of a genetic variant of the human D₄ DA receptor has revealed that mutation of a conserved valine in TMS5 (D4.4-V5.40G) results in a receptor that is unable to be activated by DA, and that has drastically decreased affinities for DA, clozapine, and olanzapine, despite having comparatively smaller or no significant decrease in affinities for haloperidol and spiperone, chlorpromazine, and raclopride, respectively [177].

Over two dozen large polymorphic variants of the human dopamine D₄ receptor gene have been identified containing anywhere from 2 to 10 copies of a variable 16-amino-acid repeat unit in the third intracellular loop [116, 178, 179]. Tandem repeats in this same region (exon III) of the D₄ gene have been identified in a large number of mammals but appear to be absent from rodents [180]. The seven-repeat variant in humans has been reported to be associated with ADHD [181–185]. The original report, [181] elaborated upon the link between the seven-repeat polymorphism and ADHD based on three lines of evidence: the role of (hypo)dopaminergic transmission in ADHD, the distribution of D₄ receptors in the brain (e.g., prefrontal cortex and striatum), and the high polymorphic variability of the D₄ receptor gene that was suggested to have functional significance. Specifically, it was proposed that the seven-repeat form of the DA D₄ receptor is hypo responsive to DA compared to the other polymorphic variants. However, an in vitro study demonstrated only a very small difference in functional coupling to G proteins (two-fold decrease in potency and no change in efficacy) for the seven-repeat polymorphism (D4.7) relative to other numbers of repeats of this polymorphism [186]. Further, this small functional difference observed in the original study has not been reproduced by other groups [187], and additional studies by the original group of repeat polymorphisms of various lengths (D4.0–D4.10) have revealed no significant differences in either pharmacology (affinity) or functional coupling efficiency (potency or efficacy) [188].

Although multiple genetic studies implicate the D₄ receptor in ADHD [185, 189–194], even if the seven-repeat polymorphism of the human DA D₄ receptor is somehow linked to ADHD, which remains controversial [192, 194–200], it appears that differences in G-protein coupling efficiency alone cannot account for the behavioral symptoms characteristic of the disorder.

7.7 CLASSIFICATION OF DOPAMINERGIC DRUGS ACCORDING TO TREATMENT CATEGORY

Since dopaminergic systems regulate a variety of cognitive and motor behaviors, drugs that target DA receptors, transporters, and metabolic enzymes are vital to the pharmacotherapeutic management of neurological and psychiatric conditions through the palliative relief of selected symptom modalities. It is possible for dopaminergic drugs to treat a plethora of clinical disorders, because relatively segregated dopaminergic neuronal pathways tend to selectively modify motor and cognitive functions and similar symptoms may be present in different disorders. While drugs are typically classified on the basis of their molecular mechanisms of action, such as agonist, partial agonist, inverse agonist, or antagonist, it is often useful to group them according to their clinical applications.

7.7.1 Parkinson's Disease

Dopamine receptor agonists provide relief to Parkinson's disease patients by replenishing the lost dopaminergic activity in the striatum that results from the death of DA-producing neurons projecting from the substantia nigra. The most common antiparkinsonian drugs are the DA precursor L-DOPA, apomorphine, pramipexole, ropinirole, and the ergolines bromocriptine and pergolide [201]. Pergolide and apomorphine are sparingly selective for D₂-like over D₁-like DA receptors, and pramipexole and ropinirole are moderately selective for D₃ over D₂ [202, 203]. Although stimulation of D₃ DA receptors may be important for treating Parkinson's disease [204, 205], pramipexole has other properties that would be beneficial for slowing the progression of neurodegeneration. For example, it is an effective antioxidant at high concentrations and can block the mitochondria transition pore at low concentrations [206, 207]. Since chronic stimulation of D₂ DA receptors is associated with potentially severe extrapyramidal side effects, like tardive dyskinesia, efforts have focused on developing D₁-selective agonists [208]. Although this strategy may lack the neuroendocrine side effects associated with stimulation of D₂ receptors, it appears that selective stimulation of D₁ receptors still has some dyskinetic side-effect liability, and there are other side effects unique to D₁ receptors as well [209]. The dilemma concerning the use of D₁-selective agonists as antiparkinsonian agents is not so much that most D₁-selective agonists are not highly selective over D₂ or that many have low efficacy. Rather it is more that most D₁-selective agonists have low orally bioavailability or they rapidly desensitize D₁ receptors, producing tolerance [208, 210, 211]. An exception to the latter is for the sparingly D₁-selective (approximately six-fold selective over D₂) agonist dinapsoline [211, 212], but it remains to be seen whether it has reduced side-effect liability in humans.

7.7.2 Schizophrenia

Historically, the treatment of psychosis has been closely correlated with the blockade of D₂ DA receptors [213, 214]. However, the D₂-selective partial agonist aripiprazole has been shown to not only be effective in treating psychosis but also be free of the extrapyramidal and neuroendocrine side effects common of typical antipsychotics (e.g., fluphenazine and haloperidol), which are due to excessive D₂ receptor blockade [215, 216]. Thus, the utility of aripiprazole appears to be that it reduces dopaminergic activity without completely blocking it. This is in line with the finding that many atypical antipsychotics have reduced extrapyramidal and neuroendocrine side-effect liability and, in general, have lower affinity for the D₂ receptors than typical antipsychotics [217–219]. Remarkably, aripiprazole also has a superior side-effect profile compared to the newer atypical antipsychotics (i.e., clozapine, olanzapine, quetiapine, risperidone, and ziprasidone) as it lacks the cardiovascular and blood dyscrasia liability and has a reduced obesity/diabetes liability.

7.7.3 Bipolar Mania, Autism, Alzheimer's Disease, and Tourette's Syndrome

In addition to their role in treating schizophrenia, some of the second-generation atypical antipsychotics are also used to treat psychosis and/or agitation and aggression of the Alzheimer's type (see [220, 221] for reviews) as well as a range of symptom modalities related to other psychiatric or neurological disorders. For example, risperidone has been shown in double-blind placebo-controlled studies to effectively treat autism spectrum disorders [222, 223]. Atypical antipsychotics have also proved effective in treating bipolar mania (see [224] for a review), which is interesting in light of the fact that intense mania and paranoid schizophrenia share many of the same clinical features [225–228]. While typical antipsychotics (e.g., pimozide and haloperidol) are approved for the treatment of the tic component of Gilles de la Tourette's syndrome, atypical antipsychotics appear to be promising alternatives (see [229, 230] for reviews).

7.7.4 Attention-Deficit Hyperactivity Disorder

The psychostimulants amphetamine and methylphenidate are used to treat ADHD. These psychostimulants are indirect dopaminergic (and norepinephrine) agonists, meaning that they increase levels of synaptic DA (and norepinephrine) by altering the activity of synaptic transporters and/or the activity and distribution of vesicular monoamine transporter-2 [231, 232]. Such agents are useful for the treatment, of ADHD, because this disorder is associated with a (noradrenergic and dopaminergic) hypofrontality that results in an attenuated drive of dopaminergic output from subcortical structures [233–236]. Animal studies suggest that selective DA D₄ antagonists may have potential as non-psychostimulant anti-ADHD drugs. Neonatal rodents injected intracisternally with 6-hydroxydopamine (and a norepinephrine transport blocker to spare noradrenergic neurons) develop a temporary juvenile hyperactive phenotype, which has been used as a model for hyperactivity in ADHD. In rats, this hyperactivity is reversed by some D₄-selective antagonists (i.e., by CP293,019, L745,870, U101,958, but not by S-18126) and exaggerated by a D₄-selective agonist (CP226,269) [237, 238]. In neonatal 6-hydroxydopamine-lesioned

wild-type but not D₄ knockout mice, both hyperactivity and reduced behavioral inhibition are evident in juveniles, and the hyperactivity is reversed by the D₄-selective antagonist PNU101,387G [239]. Although in wild-type mice the lesion-induced hyperactivity is reversed by amphetamine, the role of the D₄ receptor with respect to psychostimulant sensitivity is unclear. For example, unlesioned D₄ knockout mice, like their unlesioned non transgenic littermates, become hyperactive when challenged with methylphenidate or amphetamine, and, incidentally, D₄ knockout mice are supersensitive to the psychostimulants cocaine and methamphetamine [240]. Interestingly, unlesioned D₄ knockout mice are hypoactive in an open field, even though they have enhanced performance in the rotarod test [240]. However, D₄ knockout mice also have enhanced unconditioned fear responses [241], which might contribute to their hypoactivity in an open field.

7.7.5 Substance Use

Although DA receptors have long been pursued as targets for the potential treatment of substance use, this goal has yet to be fully realized and the findings in this field tend to be controversial. For example, systemically administered D₁-selective agonists (e.g., ABT-431) reduce cocaine-seeking behavior in rats [242, 243] and humans [208]; however, others studies indicate that the D₁-selective agonist ABT-431 attenuates the subjective effects of cocaine, including ratings of the “high” and “quality”, without affecting the number of self-administrations [244]. Paradoxically, D₁-selective antagonists have also been reported to reduce cocaine-seeking behavior by some groups [245–247] but not others [248]. Still other studies report that the D₁-like-selective antagonist SCH39166 attenuates the euphoric effects of cocaine. Although the potential for drug addiction treatment strategies involving the D₁ receptor remain unclear, an association between a D₁ receptor gene polymorphism and “sensation seeking” in alcoholic men has been reported [249].

Like D₁-selective compounds, the role of D₃-selective compounds in drug-seeking behavior is controversial. Many of the studies have focused on the D₃-selective ligand BD897. While there is some debate as to whether BD897 acts a partial agonist or an antagonist *in vivo* [250–252], in either case the effects would presumably still lead to a reduction in responsiveness relative to the endogenous full agonist dopamine. BD897 has been reported by some groups to inhibit cocaine-seeking behaviors and morphine-induced place preference in rats [253, 254] and cocaine self-administration in rhesus monkeys [250, 255]. However, others have reported that BD897 (and other D₃-selective ligands) do not inhibit cocaine-induced place preference or cocaine self-administration in rats [256, 257]. Both BD897 and the D₃-selective antagonist ST-198 disrupt nicotine-conditioned place preference [258]. In addition, the D₃-selective antagonist SB277011A has also been reported to prevent nicotine-triggered relapse of nicotine-seeking behavior [259] and to attenuate alcohol consumption in rats [260].

7.7.6 Other Uses

There is some, albeit limited, evidence that neuroleptics, in particular risperidone, may prevent self-mutilation in disorders such as autism and Lesch-Nyhan syndrome [261–264]. Antipsychotics (usually pimozide) are used to treat monosymptomatic

hypochondriacal psychoses of the dermatological type, in particular, psychosomatic delusions of parasitosis [265–269]. Agonists with high selectivity for the D₄ DA receptor have been shown recently to induce penile erection in male rats and they continue to be evaluated for possible use in erectile dysfunction [270]. This may explain the clinical observation that sublingual application of the agonist apomorphine induces penile erection [271–274]. Recent double-blind and placebo-controlled clinical trials with the moderately D₃-selective agonist ropinirole have demonstrated that it is effective in treating restless-leg syndrome [275, 276]. Dopamine receptor antagonists that do not cross the blood–brain-barrier, such as domperidone, are effective antiemetics as they block the D₂ receptors residing on the peripheral portion of the chemoreceptor trigger zone [277].

8.1 INTRODUCTION

Although serotonin (5-hydroxytryptamine; 5-HT; Fig. 8.1) was discovered more than 50 years ago, 5-HT research continues to provide fertile soil for researchers

Figure 8.1 Biosynthesis and metabolism of 5-HT. The essential amino acid tryptophan is converted in a two-step pathway to 5-HT in serotonergic neurons originating in the brain stem raphe nuclei. The first enzyme in the pathway, tryptophan hydroxylase, is the rate-limiting step of 5-HT synthesis. 5-HT is degraded by the actions of monoamine oxidase (MAO) and aldehyde dehydrogenase into its primary metabolite, 5-hydroxyindole acetic acid (5-HIAA).

attempting to unravel the mysteries of central nervous system (CNS) functioning. It has only been in recent years, however, that the importance of 5-HT in the functioning of the human brain has begun to be understood. Thus, for instance, 5-HT has been implicated in the regulation of virtually all brain functions, including perception, mood, anxiety, pain, sleep, appetite, and aggression, as well as in the pathophysiology of many psychiatric and neurological disorders [1, 2]. The involvement of 5-HT in such an extensive range of functions implies that 5-HT may function as both a classical neurotransmitter and a neuromodulator. The neuromodulatory actions of 5-HT may provide an emotional or perceptual “tone” to transmitted information. Not surprisingly, 5-HT receptors and transporters continue to be a major focus of CNS drug discovery [2]. In fact, of the 10 top CNS drugs by total sales in the year 2003, 7 modulate 5-HT neurotransmission as part of their mechanism of

action (olanzapine, tradename Zyprexa; sertraline, Zoloft; venlafaxine, Effexor; risperidone, Risperdal; bupropion, Wellbutrin; paroxetine, Paxil; and quetiapine, Seroquel). The widespread use of serotonergic drugs has led to a growing public awareness regarding the central role 5-HT plays in regulating perception, mood, and emotion. Even with this wide armamentarium of 5-HT-modulating drugs, our understanding of the basic functions of 5-HT in the CNS remains limited. However, with the cloning of at least 15 different 5-HT receptors since the early 1990s and the subsequent development of receptor-subtype knockout mice, as well as development of compounds that are more highly selective at individual receptor subtypes, a greater understanding of 5-HT function continues to emerge. This knowledge will lead to newer, improved therapies with better efficacy or side-effect profiles and an enhanced understanding of neuropsychiatric disorders. This chapter will highlight the anatomy and physiology of the CNS 5-HT system with special emphasis on the subclasses of 5-HT receptors and give a brief overview of the importance of 5-HT in disease.

8.1.1 Early History of 5-HT

Serotonin was discovered in the late 1930s by Vittorio Erspamer at the University of Pavia in Italy while he was looking for substances that were capable of causing smooth muscle contraction. Such a substance was identified in enterochromaffin cells from rabbit gastric mucosa which Erspamer named “enteramine” [3, 4]. Subsequently, at the Cleveland Clinic in the late 1940s, the laboratory of Irving Page discovered and characterized a vasoconstricting substance in serum that was produced as soon as blood coagulated [5]. The vasoconstricting substance was subsequently crystallized and christened serotonin [6]; the structure of 5-HT was elucidated in 1949 [7]. While enteramine had an extensive place in the scientific literature during that time, it was not until 1952 that it was established that enteramine was identical to 5-HT [4].

In the 1950s, Betty Twarog joined the laboratory of Irving Page and hypothesized that invertebrate neurotransmitters might also be used as neurotransmitters in vertebrates and with her previous work (published two years later) showed that 5-HT was a neurotransmitter in mussels [8]. At that time, however, 5-HT was only a serum vasoconstrictor in mammals, and there was yet no reason to believe that it would have any function as a neurotransmitter. Her research in the Page laboratory resulted in the identification of 5-HT in the brain and thus issued the emergence of 5-HT in the field of neuroscience [9]. Despite the discovery of 5-HT in nervous tissue, there was at that time considerable resistance to the notion that 5-HT had any relevance for human brain functioning (E. Costa, personal communication) although some studies suggested a prominent role for 5-HT in modulating human consciousness [10]. The landmark studies by Brodie and colleagues which demonstrated that reserpine depleted 5-HT [11, 12] and that reserpine pretreatment interfered with some actions of chlorpromazine lent strong support to the hypothesis that 5-HT was a prominent modulator of CNS functioning. It was not until a few years later when Erminio Costa discovered 5-HT in the human brain [13] that psychiatric researchers began to concede a role for 5-HT in CNS functioning. Other pivotal studies in the early evolution of our notions regarding the role of 5-HT in CNS functioning came from seminal studies by George Aghajanian and colleagues [14] which demonstrated

that lysergic acid diethylamide (LSD) modulated 5-HT release in vivo and that the raphe neurons were the main source of brain 5-HT [15]. Studies by Steven Peroutka and Solomon Snyder demonstrated that [^3H]LSD labeled 5-HT receptors in the brain [16] and that multiple 5-HT receptors existed which had distinct functions [17].

8.2 ANATOMY AND PHYSIOLOGY OF 5-HT SYSTEM

8.2.1 Anatomy of 5-HT System

In the CNS, 5-HT is almost exclusively produced in neurons originating in the raphe nuclei that are located in the midline of the brain stem along its entire rostral-caudal axis. Since the first description of large cell bodies in the brain stem midline by Ramon y Cajal and a discerning of the anatomical architecture of the projections from these cell bodies [18–20], it became apparent that 5-HT-producing neurons form the largest and most complex efferent system in the human brain. The most caudal raphe innervate the medulla and the spinal cord, while the more rostral raphe, the dorsal raphe nucleus and the medial raphe nucleus, innervate much of the rest of the CNS by diffuse projections. The dorsal raphe nucleus projects thin 5-HT fibers that preferentially innervate the cerebral cortex, as well as the thalamus, caudate and putamen, nucleus accumbens, and dopaminergic nuclei of the midbrain (substantia nigra and ventral tegmental area). Conversely, the medial raphe nucleus projects thick 5-HT fibers with large varicosities that are relatively sparse but preferentially innervate the hippocampus and other limbic structures [21, 22]. The expansiveness of the serotonergic system with virtually every cell in the brain in close proximity to a serotonergic fiber [23] makes it difficult to precisely ascertain the function of 5-HT in the brain, although one might suggest that 5-HT plays a modulatory role in CNS function.

8.2.2 Synthesis of 5-HT

Serotonin is an indolamine with a hydroxyl group at the 5 position and a terminal amine group on the carbon chain (Fig. 8.1). It is synthesized in serotonergic neurons from the essential amino acid tryptophan by two separate enzymes. The first, tryptophan hydroxylase (TPH), hydroxylates tryptophan using molecular oxygen, ascorbic acid, and biotin to synthesize 5-hydroxytryptophan (5-HTP), which is then decarboxylated into 5-HT by L-aromatic amino acid decarboxylase (AADC). TPH is the rate-limiting step in the production of 5-HT and is subject to both short-term and long-term regulatory processes. TPH can be directly activated by protein kinase A and by a calcium/calmodulin-dependent protein kinase, and the TPH gene promoter can be activated by cyclic adenosine monophosphate (cAMP) in vitro, all leading to a greater amount of 5-HT synthesis needed for heightened neurotransmission [24–26]. TPH activity can be regulated pharmacologically; 6-fluorotryptophan and *p*-fluorophenylalanine are short-lasting TPH inhibitors in vivo [27], whereas *p*-chlorophenylalanine is an irreversible inhibitor of TPH both in vivo and in vitro [28]. Inhibition of TPH results in a depletion of 5-HT and subsequent down-regulation of TPH and the 5-HT-transporter [29, 30].

In addition to TPH inhibition, 5-HT depletion can also be achieved with the use of halogenated amphetamines such as fenfluramine, formerly a prescribed appetite suppressant, and by the exclusion of tryptophan from the diet. The halogenated

amphetamines induce a rapid release of 5-HT from neurons by an unclear mechanism that may involve the disruption of the vesicular storage of the neurotransmitter resulting in an increase in the intracellular concentration of 5-HT and a reverse transport out of the nerve terminal [31, 32]. Amphetamine derivatives such as fenfluramine and methylenedioxymethamphetamine (MDMA) can also destroy 5-HT terminals leading to a long-lasting depletion of 5-HT [33, 34].

The exclusion of tryptophan from the diet can also reduce levels of 5-HT in the brain. For these studies, following a low-tryptophan diet, individuals are challenged with an amino acid-containing beverage that lacks tryptophan. These individuals display both a dramatic reduction of blood tryptophan levels and a greater than 90% reduction in 5-HT in the brain based on indirect measurements obtained by brain-imaging techniques [35]. This tryptophan depletion method has been used to study the role of 5-HT in psychiatric conditions and in the actions of psychotherapeutic agents [35]. Conversely, there are some reports that oral administration of L-tryptophan increases CNS 5-HT levels, most likely because TPH is not fully saturated [36–38]. Thus, the infusion of tryptophan has also been used experimentally to ascertain the roles of the 5-HT system in humans, though results have generally been less clear than with tryptophan depletion studies [35, 39].

8.2.3 Degradation and Reuptake of 5-HT

After release into the synaptic cleft, 5-HT is degraded, along with the catecholamine neurotransmitters, by monoamine oxidase type A (MAO_A). After 5-HT is oxidized by MAO_A, aldehyde dehydrogenase yields 5-hydroxyindoleacetic acid (5-HIAA) which is excreted in the urine. As such, many studies have measured levels of 5-HIAA in the cerebrospinal fluid (CSF), blood, and urine as a possible marker of central serotonergic function in psychiatric disorders. Most notably, decreased levels of 5-HIAA in the CSF is found in depressed patients who have recently attempted suicide [40, 41]. While the clinical utility of CSF measurements of 5-HT metabolites is limited, it has been shown that low levels of CSF 5-HIAA correlates with an increased risk of suicide following a known suicide attempt [42, 43]. In addition to MAO_A, serotonergic neurons express MAO_B intracellularly, though the affinity of this isoform for 5-HT is about 10-fold less [44]. Whether the B isoform significantly metabolizes intracellular 5-HT is unclear and it may be more likely that MAO_B is important for oxidation of other intracellular trace amines. MAO inhibitors such as phenelzine and tranylcypromine represent some of the earliest compounds useful in the treatment of depression, but despite their good efficacy, they are used less frequently today due to the risk of hypertensive crises and complex dietary restrictions.

In addition to the metabolism of extracellular 5-HT in the synaptic cleft, 5-HT is also actively transported back into the presynaptic terminal and recycled into vesicles. This reuptake of synaptic 5-HT is mediated by the 5-HT transporter (SERT), a 630-amino-acid protein with 12 transmembrane-spanning domains. SERT expression is almost entirely limited to serotonergic neurons as SERT mRNA is found in the raphe nuclei but is absent from other brain stem nuclei, while SERT protein expression is nearly ubiquitous in the CNS, consistent with the extensive nature of serotonergic projections [45–48]. SERT is extremely important clinically as the majority of antidepressants inhibit the activity of this transporter, thus prolonging serotonergic signaling. These include the selective 5-HT reuptake

inhibitors (SSRIs), such as fluoxetine, sertraline, and paroxetine, which are among the most widely prescribed antidepressants, as well as the older class of antidepressants known as tricyclics, such as amitriptyline and clomipramine. The SSRIs were given their name based on their ability to bind relatively selectively to SERT over the norepinephrine and dopamine transporters, in contrast to the tricyclic antidepressants which vary in their relative selectivities and thus inhibit the reuptake of multiple neurotransmitters, most notable norepinephrine. In addition to psychotherapeutic agents, several drugs of abuse interfere with SERT activity, along with other transporters. These include cocaine, amphetamines, and MDMA; the effects of these agents on SERT have been recently reviewed [49].

8.3 5-HT RECEPTORS

8.3.1 5-HT Receptor Nomenclature

The extraordinary diversity of CNS functions regulated by 5-HT underscores the complexity of the 5-HT system. This complexity is due, in part, to the vastness of the serotonergic projections from the raphe nuclei but is also due to the molecular diversity and differential cellular distribution of the multiple 5-HT receptor subtypes that are expressed in the brain. At least 14 different 5-HT receptors encoded by distinct genes have been identified since the advent of molecular cloning techniques and are divided into seven major classes: 5-HT₁, 5-HT₂, 5-HT₃, 5-HT₄, 5-HT₅, 5-HT₆, and 5-HT₇ [50] (Fig. 8.2). Most of these classes have multiple subtypes, including the 5-HT₂ class that is divided into 5-HT_{2A}, 5-HT_{2B}, and 5-HT_{2C} [50, 51]. With the exception of 5-HT₃ receptors, which are ligand-gated ion channels [52, 53], 5-HT receptors are members of the G-protein-coupled receptor superfamily (Fig. 8.3).

Prior to molecular cloning, receptors were distinguished pharmacologically and as early as 1954 there was evidence of more than a single 5-HT receptor [54]. In 1957, Gaddum and Picarelli reported the existence of two distinct 5-HT receptor subtypes in the periphery which they called 5-HT_M and 5-HT_D based on their antagonists, morphine and dibenzyline, respectively [55]. In 1978, Leysen and colleagues discovered a serotonergic component of neuroleptic receptors labeled with [³H]spiperone [56], and further studies in rat brain homogenates revealed multiple 5-HT receptor subtypes in the CNS [16]. The 5-HT₁ receptor was labeled by [³H]5-HT, whereas the 5-HT₂ receptor (that corresponded to 5-HT_D) was labeled by the dopamine receptor ligand [³H]spiperone [16]. The M receptors were renamed 5-HT₃ receptors [57] and were found to be the only ionotropic subtype of 5-HT receptor [52, 58]. Soon after, heterogeneity of the 5-HT₁ receptor class became apparent as 5-HT_{1A} receptors could be distinguished pharmacologically from 5-HT_{1B} receptors (equivalent to the human 5-HT_{1D} receptor) [59]. A third type of 5-HT₁ receptor, the 5-HT_{1C} receptor, was demonstrated by autoradiographic techniques in the porcine choroid plexus through its high affinity for [³H]mesulergine and [³H]5-HT [60]. However, after the 5-HT_{1C} receptor was cloned, it was shown to possess 75% sequence homology to the 5-HT₂ receptor (now called 5-HT_{2A}) and, like the 5-HT₂ receptors, was also coupled to a phosphoinositol second messenger system instead of to the inhibition of adenylyl cyclase as are the members of the 5-HT₁ family [61]. The current 5-HT receptor nomenclature was adopted in 1994 and dictates that receptor classification should meet operational (drug-related characteristics), transductional (effector systems), and

Figure 8.2 Dendrogram of 5-HT receptor subtypes. The relationships among the sequences of the various human 5-HT receptors are represented as a dendrogram. Groupings were calculated using the CLUSTAL algorithm [330] with the PAM 250 residue weight matrix. Horizontal axis indicates percentage difference among 5-HT receptors.

structural (genetic and amino acid sequence) criteria [62] (Fig. 8.2). As such, 5-HT receptors are now allocated to seven distinct families, 5-HT₁ to 5-HT₇, with multiple subtypes in some families (Table 8.1).

8.3.2 5-HT₁ Receptor Family

Among the seven classes of 5-HT receptors, the 5-HT₁ class is the largest and is comprised of five receptor types, with the 5-HT_{1A}, 5-HT_{1B}, and 5-HT_{1D} characterized by a high affinity for 5-carboxamido-tryptamine (5-CT), the 5-HT_{1E} and 5-HT_{1F} characterized by a low affinity for 5-CT, and all five having a nanomolar affinity for 5-HT (Table 8.1). The original 5-HT_{1C} receptor is now classified as the 5-HT_{2C} receptor [61]. The genes encoding 5-HT₁ receptors have been cloned in both humans and rodents, allowing the demonstration that they all belong to the G-protein-coupled receptor superfamily with the characteristic seven hydrophobic transmembrane domains. All of the 5-HT₁ receptors interact with $G\alpha_i/G\alpha_o$ G proteins to inhibit adenylyl cyclase and modulate ion channels [63, 64]. Following is an overview of each member of the 5-HT₁ receptor family.

8.3.2.1 5-HT_{1A} Receptors. The 5-HT_{1A} receptors are particularly relevant to the antidepressant and anxiolytic responses in human beings. They are located presynaptically on serotonergic neurons in the raphe nuclei, where they act as

Figure 8.3 Model of a serotonergic neuron and synapse. Diagram of a serotonergic neuron originating from the brain stem raphe nuclei. 5-HT_{1A} receptors function both as autoreceptors on the serotonergic cell body and as postsynaptic receptors. Tryptophan and TPH are transported to the synapse where the synthesis of 5-HT is initiated. 5-HT_{1D} receptors function as autoreceptors on the presynaptic side of the synapse. Most 5-HT receptors are G-protein-coupled receptors and are located postsynaptically to serotonergic neurons. The 5-HT₃ receptor is the exception as it is a ligand-gated ion channel. The 5-HT_{1E} and 5-HT_{1F} receptors are also located postsynaptically and are coupled to G_i (not shown). The G-protein coupling of the 5-HT_{5A} receptor is still unclear. AC, adenylyl cyclase; PLC, phospholipase C; SERT, serotonin transporter; GIRK, G-protein-coupled inwardly rectifying potassium channels; TPH, tryptophan hydroxylase; IP₃, inositol trisphosphate; DAG, diacylglycerol.

TABLE 8.1 5-HT Receptors, Prototypical Ligands, and Clinical Use

Receptor	Prototypical Agonist	Prototypical Antagonist	Therapeutic Indications	Commonly Prescribed Medications and Drugs of Abuse
5-HT _{1A}	8-OH-DPAT	WAY100635	Anxiety, depression, neuroprotection	Buspirone (agonist); clozapine (partial agonist)
5-HT _{1B}	Sumatriptan	SB 224289	Anxiety, depression, migraine headache	Sumatriptan
5-HT _{1D}	Sumatriptan	BRL 15572	Migraine headache, depression	Sumatriptan
5-HT _{1E}	5-HT	None	Unknown	None
5-HT _{1F}	LY334370	None	Migraine headache	Sumatriptan
5-HT _{2A}	DOB	M100907	Schizophrenia, depression, anxiety, sleep disorders	LSD (agonist); atypical antipsychotic drugs and many antidepressants (antagonists)
5-HT _{2B}	BW 723C86	SB 204741	None	Pergolide, fenfluramine, and MDMA (agonists); clozapine (antagonist)
5-HT _{2C}	WAY-629	SB 206553	Appetite suppression	LSD (agonist); tricyclic antidepressants (antagonists)
5-HT ₃	None	Odansetron	Emesis	Odansetron
5-HT ₄	BIMU 8	SB 204070	Cognition enhancement, gastrointestinal motility	Cisapride
5-HT ₅	None	None	Unknown	LSD (agonist)
5-HT ₆	2-Ethyl-5-methoxy- <i>N,N</i> -dimethyltryptamine	MRS-245	Cognition enhancement	Many antidepressants and atypical antipsychotic drugs (antagonists)
5-HT ₇	None	SB 258719	Insomnia, depression	Antidepressants and many atypical antipsychotic drugs

autoreceptors to inhibit the firing rate of 5-HT neurons. The 5-HT_{1A} receptors are also located postsynaptically in limbic and cortical regions, where they may also attenuate firing [65] (Fig. 8.3). The highest densities of 5-HT_{1A} receptors in the brain are in the hippocampus, septum, amygdala, and cortical limbic areas whereas the 5-HT_{1A} receptors located in the raphe nuclei correspond to somatodendritic autoreceptors [66].

On serotonergic neurons, somatodendritic 5-HT_{1A} autoreceptors exert a negative-feedback influence on firing activity, when activated by an excess amount of 5-HT or by an exogenous agonist, by hyperpolarizing serotonergic neurons, thereby slowing down their baseline pacemaker firing activity [67–72]. Because 5-HT release is proportional to the firing rate of 5-HT neurons, excessive activation of 5-HT_{1A} autoreceptors results in a decrease of 5-HT release in projecting structures [73]. Likewise, postsynaptic 5-HT_{1A} receptors, which are particularly abundant in limbic structures, also have an inhibitory action on neuronal firing [72] (Fig. 8.3). Thus, the systemic administration of a 5-HT_{1A} receptor agonist, such as buspirone, results in a net decrease of 5-HT transmission at all postsynaptic 5-HT receptors, except those of the 5-HT_{1A} subtype.

The prototypic 5-HT_{1A} receptor agonist ligand is the aminotetralin derivative 8-OH-DPAT, though the azapirones probably represent the largest class of 5-HT_{1A} receptor ligands [74]. The azapirones are full agonists at 5-HT_{1A} autoreceptors and are generally, but not exclusively, partial agonists at postsynaptic 5-HT_{1A} receptors (Table 8.1). Effects of 5-HT_{1A} receptor-selective ligands on animal behavior have been extensively studied. Partial agonists (buspirone, ipsapirone, gepirone) and to a certain degree full 5-HT_{1A} receptor agonists (8-OH-DPAT) result in an anxiolytic-like effect [75, 76]. Of these drugs, only buspirone is clinically approved as an anxiolytic. With prolonged 5-HT_{1A} receptor agonist treatment, however, serotonergic neurons gradually recover their normal firing rate as a result of 5-HT_{1A} autoreceptor desensitization [67, 77], a process common among G-protein-coupled receptors [78]. This desensitization, however, is thought to be involved in the therapeutic action of 5-HT_{1A} receptor partial agonists as, like the SSRIs, there is a delay in the onset of therapeutic effects. The onset of action may actually be due to an increased activation of postsynaptic 5-HT_{1A} receptors occurring only after the 5-HT_{1A} autoreceptors are desensitized and the serotonergic neurons regain their normal level of firing activity. At this point, the summed effects of a normalized level of synaptic 5-HT and the exogenous 5-HT_{1A} agonist can be exerted on postsynaptic 5-HT_{1A} receptors.

In addition to anxiety, 5-HT_{1A} receptors may also be important in depression, aggression, obsessive-compulsive disorders, posttraumatic stress disorder, sexual behavior, appetite control, thermoregulation, and cardiovascular function [79–83]. Indeed, a deficiency in the 5-HT_{1A} receptor has been reproducibly found in the limbic system in mood disorders [83, 84], and further studies have indicated that low 5-HT_{1A} receptor levels may represent a risk factor in many psychiatric disorders [85]. As such, the generation of 5-HT_{1A} receptor knockout mice was of high priority and, in 1998, three groups simultaneously reported the generation of knockout mice in different genetic backgrounds [86–88]. All of the initial studies on the behavior of these 5-HT_{1A} receptor knockout mice found an anxiety-like phenotype in these mice. Importantly, anxiety was apparent not only in homozygote but also in heterozygote 5-HT_{1A} receptor knockout mice, indicating that a partial receptor deficit is sufficient to elicit the phenotype [86–88]. This suggested that transcriptional and posttranslation

mechanisms of 5-HT_{1A} receptor regulation, such as receptor downregulation, may contribute to the pathogenesis of some psychiatric disorders. For additional review of 5-HT_{1A} receptor knockouts as a model for anxiety, see Toth, 2003 [85].

8.3.2.2 5-HT_{1B} and 5-HT_{1D} Receptors. Due to the considerable similarity between 5-HT_{1B} and 5-HT_{1D} receptors, they will be discussed together. Indeed, the similarity between these receptors and interspecies differences has resulted in a complicated history. As such, the 5-HT_{1B} receptor was initially claimed to exist only in rodents (rat, mouse, and hamster) [59, 65], whereas in humans, two distinct receptors had been cloned and were named 5-HT_{1D α} and 5-HT_{1D β} [89, 90]. The human 5-HT_{1D α} and 5-HT_{1D β} receptors display about 77% sequence homology and their pharmacological properties are nearly indistinguishable [90]. The subsequent cloning of the rodent 5-HT_{1B} receptor, however, revealed that the 5-HT_{1B} receptor was homologous to the human 5-HT_{1D β} receptor [90–94]. The same nomenclature is now recommended for this receptor in all mammalian species; thus, the 5-HT_{1D β} receptor in humans was renamed h5-HT_{1B}, and the rat 5-HT_{1B} receptor, r5-HT_{1B} [93, 94]. Likewise, the human 5-HT_{1D α} receptor was renamed 5-HT_{1D} [93, 94]. There are, interestingly, a few key pharmacological differences between the rodent and human 5-HT_{1B} receptors. For example, some β -adrenergic antagonists, such as (–)propranolol, bind to r5-HT_{1B} receptors with a much higher affinity than to h5-HT_{1B} receptors [90, 91] due to single-amino-acid difference (asparagine vs. threonine) in the seventh transmembrane domain of the receptors [95, 96].

The 5-HT_{1B} receptor binding sites have been detected by autoradiography and immunohistochemistry with high densities in the basal ganglia, particularly in the globus pallidus and substantia nigra [66, 97–99]. The distribution of the 5-HT_{1B} receptor binding sites found in rat brain was similar to that of the 5-HT_{1D β} receptor binding sites observed in human [98, 100–102]. The 5-HT_{1B} receptor binding sites are also found at lower densities in the cerebral cortex, amygdala, hypothalamus, and spinal cord [66, 99]. The 5-HT_{1B} receptors are predominantly found at the presynaptic terminal where they can function as both autoreceptors on serotonergic neurons and heteroreceptors on nonserotonergic neurons to modulate neurotransmitter release [103–109] (Fig. 8.3). Thus, activation of 5-HT_{1B} receptors has been reported to inhibit the release of 5-HT in the hippocampus and frontal cortex [110–112]. Moreover, as heteroreceptors, 5-HT_{1B} receptor activation has been shown to have an inhibitory effect on the release of γ -aminobutyric acid (GABA), acetylcholine, glutamate, and dopamine [113–115]. Indeed, while 5-HT_{1B} receptors have been traditionally associated with 5-HT autoreceptor function, it is becoming clear that most of the 5-HT_{1B} receptors in the brain are expressed on nonserotonergic neurons [113].

The 5-HT_{1B} receptors have been shown to be involved in several physiological functions, behaviors, and psychiatric diseases, including locomotor activity, drug abuse reinforcement, migraine, anxiety states, and aggressive behavior [116–121] (Table 8.1). For example, 5-HT_{1B} receptor knockout mice were reported to exhibit increased aggressive behavior toward other mice in resident–intruder aggression tests [121, 122] and have also been reported to show decreased anxiety and behavioral hyperactivity manifested as increased exploratory behavior [122, 123]. This increased aggressive behavior and hyperactivity may suggest that 5-HT_{1B} receptors play a role in impulse control. The findings with the 5-HT_{1B} receptor knockout mice correlate

with the findings that certain 5-HT_{1B} receptor agonists (serenics) have antiaggressive properties [124]. The 5-HT_{1B} receptor has also been implicated in the reinforcing and aversive actions of cocaine in rodents by both pharmacological and null mutation strategies [125]. For example, 5-HT_{1B} receptor knockout mice have also shown increased vulnerability and altered responses to several drugs of abuse such as increased voluntary self-administration of cocaine and increased locomotor response to cocaine [126]. In addition, several investigators have reported increased ethanol consumption in 5-HT_{1B} receptor knockout mice [127, 128]. Interestingly, behavior studies have also demonstrated that 5-HT_{1B} receptor agonists induce a learning deficit [129] whereas a 5-HT_{1B} receptor antagonist enhances learning consolidation [130]. The precise role of the 5-HT_{1B} receptor, however, remains largely unknown and is complicated by the lack of selective pharmacological agents and by the contradictory effects of 5-HT_{1B} autoreceptors and heteroreceptors.

Like the 5-HT_{1B} receptor, the ultimate clinical significance of the 5-HT_{1D} receptor remains largely unknown again due to the lack of selective drugs (Table 8.1). There has been speculation, however, that these receptors might be involved in anxiety, depression, and other neuropsychiatric disorders, but this remains, for the most part, unsubstantiated [113]. Another complication is that studies in all species are faced by the low levels of the 5-HT_{1D} versus 5-HT_{1B} receptor in brain [99]. Studies using nonselective radioligands in the presence of more selective inhibitors of other receptor sites have suggested that 5-HT_{1D} receptors are located in various brain regions but at higher levels in the basal ganglia but also in the hippocampus and cortex [99, 131]. There is also clear evidence from receptor autoradiography and in situ hybridization studies that the 5-HT_{1D} receptor, like the 5-HT_{1B} receptor, is located presynaptically on both serotonergic and nonserotonergic neurons [131]. Thus, 5-HT_{1D} receptors may also have autoreceptor and heteroreceptor actions on the inhibition of neurotransmitter release (Fig. 8.3).

The 5-HT_{1D} receptors have been implicated in the pathophysiology of migraine because 5-HT_{1D} receptor agonists, such as sumatriptan, have remarkable efficacy in treating migraine. However, there is considerable controversy regarding the nature of the actual 5-HT receptors involved in migraine since sumatriptan binds nearly equally well at 5-HT_{1D} and 5-HT_{1B} receptors [132] and also binds to 5-HT_{1F} sites [133]. It has been suggested that 5-HT_{1B} receptors may be primarily involved in neurogenic inflammation [134] due to their preponderance in neuronal tissue, whereas 5-HT_{1D} receptors may be more involved in vasoconstriction [135].

8.3.2.3 5-HT_{1E} Receptors. The 5-HT_{1E} receptor was first detected in radioligand binding studies using [³H]5-HT while masking the other 5-HT₁ subtypes known at that time (5-HT_{1A}, 5-HT_{1B}, 5-HT_{1C}), leading to a biphasic displacement curve to 5-CT [136, 137]. One component of these curves was associated with 5-HT_{1D} binding, whereas the other was attributed to a novel receptor, the 5-HT_{1E} receptor [137]. Later, the 5-HT_{1E} gene was cloned by several independent laboratories from human genomic libraries [138, 139] and a human complementary deoxyribonucleic acid (cDNA) library [140] and found to have a pharmacology similar to that described by Teitler's group [137].

The protein distribution of 5-HT_{1E} receptor in the brain is inconclusive because no selective ligands or antibodies are available, though autoradiographic studies have been performed while masking other 5-HT₁ receptors [99, 141, 142]. These studies

indicate that in all species higher levels of these binding sites were present in the cortex, caudate, and putamen, but detectable levels were found in other areas, including hippocampus and amygdala. The 5-HT_{1E} receptors appear to have a postsynaptic location [142].

Currently, nothing is known about the physiological function of the 5-HT_{1E} receptor. This is partly due to the unavailability of selective pharmacological tools, but the lack of an animal model also makes it hard to explore the function of this receptor (Table 8.1). A high level of expression of 5-HT_{1E} receptor messenger ribonucleic acid (mRNA) in the hippocampus and olfactory [143] may suggest a role for this receptor in the regulation of memory, learning, and emotion [144, 145].

8.3.2.4 5-HT_{1F} Receptors. The newest 5-HT₁ receptor to be cloned is the human 5-HT_{1F} receptor. This 5-HT_{1F} receptor gene was originally detected in the mouse on the basis of its sequence homology with the 5-HT_{1B} and 5-HT_{1D} receptor subtypes [146]. The human 5-HT_{1F} gene followed shortly afterward [133]. Initial studies located 5-HT_{1F} mRNA in the mouse and guinea pig brain using in situ hybridization with an abundance in the hippocampus, cortex, and dorsal raphe nucleus [133, 146, 147]. Autoradiography studies using [³H]sumatriptan in the presence of 5-CT demonstrated a good correlation with the distribution of 5-HT_{1F} mRNA. [131, 148–150]. The brain distribution of 5-HT_{1F} binding sites labeled by a novel, selective 5-HT_{1F} radioligand, [³H]LY334370, was reported and demonstrated a low abundance and fit with the restricted distribution of this receptor subtype [151].

The clinical significance of 5-HT_{1F} receptors is unknown at this time. The binding of sumatriptan at this receptor population suggests that 5-HT_{1F} receptors may be involved in migraine [133], and a single clinical trial showed that a 5-HT_{1F} agonist had antimigraine actions, although the compound was later dropped due to toxicity (D. Nelson, personal communication) [152] (Table 8.1). Recent studies show that 5-HT_{1D} receptors are the dominant species in human cerebral blood vessels, but they further show that 5-HT_{1F} receptors are expressed in both neural and vascular tissue [134, 135].

8.3.3 5-HT₂ Receptor Family

The 5-HT₂ receptor family consists of three receptor subtypes, 5-HT_{2A}, 5-HT_{2B}, and 5-HT_{2C} receptors, which are similar in terms of their molecular structure, pharmacology, and signal transduction pathways [51]. The 5-HT_{2A} receptor was originally designated as the 5-HT_D receptor and later the 5-HT₂ receptor [16, 55, 62]. The original 5-HT_{1C} receptor was renamed the 5-HT_{2C} receptor after it was cloned because of significant homology and coupled effector systems as the 5-HT_{2A} receptor [61]. Another 5-HT₂-like receptor, based on similar pharmacology, was found in the stomach fundus [153, 154] and when cloned it was found to be structurally related to the 5-HT_{2A} and 5-HT_{2C} receptors and was thus named 5-HT_{2B} [155, 156]. The members of the 5-HT₂ family of receptors are all G-protein-coupled receptors and have high degree of homology within the seven transmembrane domains but are structurally distinct from other 5-HT receptors [157]. The 5-HT₂ receptors interact primarily with the G α_q class of G proteins to result in the activation of phospholipase C and the mobilization of intracellular calcium [158], and stimulation of these receptors causes cell excitation.

8.3.3.1 5-HT_{2A} Receptors. The distribution of 5-HT_{2A} receptors in the CNS has been extensively characterized by autoradiography, in situ hybridization, and immunohistochemistry. Receptor autoradiography studies using [³H]-spiperone, [³H]-ketanserin, [¹²⁵I]-DOI, and [³H]-MDL 100907 as radioligands have demonstrated high levels of 5-HT_{2A} receptor binding sites in many forebrain regions, particularly various cortical regions, with lower levels in the basal ganglia and hippocampus [159–162]. There has generally been close concordance between the distribution of 5-HT_{2A} receptor binding sites, mRNA, and receptorlike immunoreactivity [163–168], suggesting that the cells expressing 5-HT_{2A} receptors are located in the region where the receptors are present and are thus located postsynaptically relative to the serotonergic neuron (Fig. 8.3).

The 5-HT_{2A} receptors are particularly abundant in the pyramidal neurons primarily from cortical layers IV and V [164, 165, 168]. Within the cortical pyramidal neurons, 5-HT_{2A} receptors are preferentially sorted to the apical dendrites [164, 165, 168] where information from the dendritic tree integrates before descending onto the soma and into the axon [169]. The 5-HT_{2A} receptors in the apical dendrites mediate the 5-HT-induced enhancement of excitatory postsynaptic potential (EPSP) in pyramidal neurons, which may be responsible for the psychotomimetic effects of some hallucinogens [170, 171].

The 5-HT_{2A} receptors are essential for mediating a large number of physiological processes in the periphery and in the CNS, including platelet aggregation, smooth muscle contraction, and modulation of mood and perception [51]. Many drugs of diverse therapeutic classes mediate their actions, at least in part, by interactions with 5-HT_{2A} receptors. Most but not all hallucinogens [172], including LSD and *N,N*-dimethyltryptamine, function as agonists at 5-HT_{2A} receptors [173], while all clinically approved atypical antipsychotic drugs are potent 5-HT_{2A} receptor antagonists [174] (Table 8.1). In vivo studies have demonstrated that 5-HT_{2A} receptors mediate 5-hydroxytryptophan-induced head twitch behavior [175–179], wet dog shakes [176, 180], and urinary bladder contraction [181]. It was shown that the potency with which 5-HT₂ receptor antagonists inhibit agonist-induced head shakes closely correlated with their affinity for the 5-HT_{2A} receptor binding site but not other binding sites, including the 5-HT_{2C} receptor binding site [178, 182]. Furthermore, 5-HT_{2A} receptor-selective antagonists such as MDL 100907 inhibited the head shake response while 5-HT_{2B} and 5-HT_{2C} receptor-selective antagonists (SB 200646A) did not [178, 183]. In humans, a direct linear correlation has been demonstrated between the abilities of a variety of hallucinogens to induce hallucinations and their abilities to bind to 5-HT_{2A} receptors [184]. Indeed, the actions of psilocybin in humans can be blocked by either ketanserin or risperidone but not by haloperidol [185], indicating that the actions of hallucinogens in humans are mediated via activation of 5-HT_{2A} receptors.

The importance of 5-HT_{2A} receptors in schizophrenia was recognized as early as 1954 [10, 54] with further support coming with the discovery that reserpine, a drug with some efficacy in treating schizophrenia, depletes 5-HT [11, 12] and the demonstration of a serotonergic component of antipsychotic drug binding in 1978 [56]. The discovery that clozapine, a drug highly effective in treating schizophrenia [186], is a 5-HT_{2A} receptor antagonist [187] that downregulates 5-HT_{2A} receptors [188, 189] further reinforced the hypothesis that 5-HT_{2A} receptor blockade may be beneficial in schizophrenia. It was soon discovered that atypical antipsychotic drugs, as a group, bound with higher affinity to 5-HT_{2A} receptors than to dopamine

D₂ receptors [190]. Indeed, atypical antipsychotic drugs can be classified based on a 5-HT_{2A}-D₂ affinity ratio of >1, while the typical antipsychotic drugs all have 5-HT_{2A}-D₂ affinity ratios <1 [174]. Interestingly, risperidone and olanzapine, both of which have high 5-HT_{2A} receptor blocking activity relative to their D₂ affinity, have greater efficacy for treating negative symptoms of schizophrenia and produce fewer extrapyramidal side effects than haloperidol [191, 192]. Selective 5-HT_{2A} receptor antagonists (especially MDL 100907 and SR46349B) have shown promise in animal models to be predictive of atypical antipsychotic action [193] and have demonstrated efficacy in treating schizophrenia [194]. Additional evidence highlighting the role of 5-HT_{2A} receptors in schizophrenia comes with evidence of an association between schizophrenia and treatment outcome and certain polymorphic variants of the 5-HT_{2A} receptor [195]. To our knowledge selective 5-HT_{2A} antagonists represent the only known clinically effective antipsychotic drugs which do not have appreciable affinity for dopamine D₂ receptors [2].

More recently, 5-HT_{2A} receptors have been implicated as mediating viral entry of the JC virus—the causative agent of progressive multifocal leukoencephalopathy (PML) [196]. In these studies, the JC virus was shown to require intact 5-HT_{2A} receptors for viral entry into neuronal cells and 5-HT_{2A}-selective antagonists were able to block viral entry. These results imply that 5-HT_{2A} antagonists may represent novel treatments for PML, which is the main cause of human immunodeficiency virus (HIV) dementia [197].

8.3.3.2 5-HT_{2B} Receptors. The 5-HT_{2B} receptors are found in many organs, including the stomach fundus [198], vascular smooth muscle [199], heart valves [200], spinal cord [201], and at low levels in some brain regions [202]. Indeed, the presence of the 5-HT_{2B} receptors in the brain has been controversial, but it is now clear that 5-HT_{2B} receptor mRNA and protein are expressed with very limited distribution but are potentially of functional importance [153, 203–205]. By immunohistochemistry, 5-HT_{2B} receptor–like immunostaining was reported to be limited to only a few brain regions, particularly the cerebellum, lateral septum, dorsal hypothalamus, and medial amygdala [204]. In this study, the cells expressing 5-HT_{2B} receptor–like immunoreactivity have a neuronal and not astrocytic morphology [204].

There are little available data on the functional effects of activation of the central 5-HT_{2B} receptor. It has been suggested, however, that the 5-HT_{2B} receptor has a role in anxiety as the nonselective 5-HT₂ receptor agonist BW723C86 is reported to have anxiolytic properties in the rat social interaction test that can be reversed by a selective 5-HT_{2B} receptor antagonist [206, 207]. Interestingly, BW723C86 has an anxiolytic effect when injected directly into the medial amygdala [208], which contains detectable amounts of 5-HT_{2B} receptor–like immunoreactivity [204]. Outside of the CNS, activation of the 5-HT_{2B} receptor has recently been shown to mediate the valvulopathic side effects of the now-banned appetite suppressant fenfluramine [209] (Table 8.1). It is likely that other pharmaceuticals and drugs of abuse may activate 5-HT_{2B} with potential to lead to valvular heart disease [210].

8.3.3.3 5-HT_{2C} Receptors. The 5-HT_{2C} receptor was originally identified as a [³H]5-HT binding site in the choroid plexus of various species that could also be labeled by [³H]mesulergine and [³H]LSD but not by [³H]ketanserin [60]. Originally this site was named the 5-HT_{1C} receptor because of its high affinity for [³H]5-HT

[211] but was reclassified as the 5-HT_{2C} receptor after the receptor was cloned and further characterized [212]. The mouse 5-HT_{2C} receptor was partially cloned in 1987 [213], and this was shortly followed by the sequencing of full-length clones in rat, mouse, and human [61, 214, 215]. Unlike the 5-HT_{2A} and 5-HT_{2B} receptors, there is very little 5-HT_{2C} receptor expression outside of the CNS. Autoradiographic studies have provided a detailed map of 5-HT_{2C} receptor binding sites in rat and other species [216–218]. In addition to the very high levels in the choroid plexus, 5-HT_{2C} receptor binding sites are widely distributed in the cortex, basal ganglia, hippocampus, and hypothalamus [217]. Due to correlation between 5-HT_{2C} receptor mRNA and receptor binding sites, the 5-HT_{2C} receptor is clearly located postsynaptically [166, 219] (Fig. 8.3).

The 5-HT_{2C} receptors have been shown to undergo a form of posttranslational regulation known as RNA editing [220]. RNA editing in mammalian systems generally involves the conversion of adenosine residues to inosines at the mRNA level [221] and has the potential to result in multiple protein isoforms that may have altered functions. Editing of the 5-HT_{2C} receptor was discovered by comparing sequences from genomic DNA and cDNAs from the rat striatum [220] which showed five different adenosines that could be edited and predicted the formation of protein isoforms with up to three amino acids changed in the second intracellular loop of the receptor [222–224]. The genomic DNA predicted isoleucine, asparagine, and isoleucine at positions 157, 159, and 161 (5-HT_{2C-INI}), whereas the cDNA library predicted valine, serine, and valine at those positions (5-HT_{2C-VSV}). Further analysis of cDNA sequences isolated from rat brain revealed the tissue-specific expression of 7 major 5-HT_{2C} receptor isoforms that are encoded by 11 distinct RNA species [224]. Because the second intracellular loop has been implicated in receptor activation and G-protein coupling [225, 226], it is likely that these isoforms have different intracellular signaling properties. Indeed, many studies have demonstrated altered signaling properties of 5-HT_{2C}-editing isoforms [227]. The *in vivo* functional consequences of RNA editing of the 5-HT_{2C} receptor are unknown and create a challenge of isolating the function of a single, specific isoform, although several studies have suggested alterations in RNA editing in various psychiatric illnesses, including schizophrenia [228] and suicide [229], and by stress and antidepressant administration [230].

Both pharmacological and genetic approaches to the analysis of 5-HT_{2C} receptor function have revealed that it is involved in the regulation of a wide range of behavioral and physiological processes, including regulation of the dopaminergic system and regulation of appetite, and plays a role in drug abuse, anxiety, and depression [231] (Table 8.1). Activation of 5-HT_{2C} receptors has been shown to have significant inhibitory effects on both the limbic and striatal dopamine pathways that may contribute to the efficacy or side-effect profile of dopaminergic agents such as antipsychotics [232–236]. Indeed, many antipsychotic drugs have high affinities for 5-HT_{2C} receptors [237] where they function as inverse agonists [238]. It is also possible that the influence 5-HT_{2C} receptor agents have on mesolimbic dopamine transmission could modulate the reinforcing and behavioral effects of drugs of abuse [239–241]. The 5-HT_{2C} receptors also contribute substantially to the serotonergic suppression of feeding as 5-HT_{2C} agonists produce hypophagia that is blocked by antagonists [242, 243]. In addition, 5-HT_{2C} receptor knockout mice were found to have elevations of body weight and adiposity [244] likely related to chronically increased food intake [245]. Indeed, selective 5-HT_{2C} receptor agonists have shown promise as anorectic

agents in humans [246] and many 5-HT_{2C} receptor-selective agonists which avoid interactions with 5-HT_{2B} receptors are currently in testing.

8.3.4 5-HT₃ Receptors

In contrast to the other known 5-HT receptors that are all members of the G-protein-coupled receptor superfamily, the 5-HT₃ receptor belongs to the superfamily of ligand-gated ion channels. Responses mediated by 5-HT₃ receptors have been studied since the 1950s, but due to the lack of pharmacological approaches to study this receptor, it was not until recently that the 5-HT₃ receptor was appreciated to be the originally described 5-HT_M receptor [52, 55, 247, 248]. The 5-HT₃ receptor channel complex, like other members of this superfamily, is a pentameric assembly of individual protein subunits, where each subunit is thought to have four transmembrane domains [249]. When the first gene encoding the 5-HT₃ receptor (the 5-HT_{3A} receptor subunit) was cloned and expressed in heterologous expression systems, it formed functional homomeric channels [52]. A shorter splice variant of the 5-HT_{3A} receptor subunit has also been cloned from mouse, rat, and guinea pig and was shown to be the most abundant, and in humans the only, form in the CNS [247, 248, 250]. However, no functional differences between these alternatively spliced 5-HT_{3A} receptor subunits have been found to date [251]. In 1998, a second 5-HT₃ receptor subunit, the 5-HT_{3B} receptor subunit, was cloned [53, 252]. This subunit does not form functional channels on its own but requires coassembly with the 5-HT_{3A} receptor subunit for its function, yielding a 5-HT₃ receptor with significantly larger single-channel conductance [53, 253]. There is currently conflicting lines of evidence concerning whether the 5-HT_{3B} subunit is expressed in the CNS forming heteromeric receptor complex [251].

The 5-HT_{3A} receptor subunit is ubiquitously expressed in the CNS at low levels, and 5-HT₃ receptors are thought to participate in a variety of physiological processes, including cognitive processing [249]. In the CNS, 5-HT₃ receptors are expressed in the cortex, hippocampus and amygdala, medulla oblongata, spinal cord, and to a lesser extent nucleus accumbens, striatum, and substantia nigra [254]. On a cellular level, postsynaptic 5-HT₃ receptors mediate fast excitatory synaptic transmission in rat neocortical interneurons and amygdala [255, 256] and are also present on presynaptic nerve terminals, where they are thought to mediate or modulate neurotransmitter release [257, 258] (Fig. 8.3). The 5-HT₃ receptor antagonists, such as ondansetron, are clinically effective in the treatment of chemotherapy-induced or radiation-induced nausea and vomiting [259], whereas they are ineffective against motion sickness and apomorphine-induced emesis [260] (Table 8.1). Preclinical studies have suggested that 5-HT₃ receptor antagonists may also enhance memory and be of benefit in the treatment of anxiety, depression, and dementia [260]. One of the most attractive features of 5-HT₃ antagonists is their general lack of undesirable side effects characteristic of many psychotherapeutic agents. Very little is known about the possible therapeutic application of 5-HT₃ agonists, however, though it seems that some partial agonists may be anxiolytic [261].

8.3.5 5-HT₄ Receptors

The 5-HT₄ receptor was initially identified in cultured neurons from mouse colliculi and guinea pig brain by stimulation of adenylyl cyclase activity [262, 263]. This was

thus the first 5-HT receptor shown to couple positively to adenylyl cyclase, though the ability of 5-HT to stimulate adenylyl cyclase had been known for a number of years prior [264, 265]. Several splice variants of the 5-HT₄ receptors have been cloned, differing in the length of their C-terminal tails [266, 267]. In heterologous expression systems, these receptors present some functional and pharmacological differences. In particular, the length of the C-terminal sequence of the receptor was shown to be implicated in its constitutive activity [268].

The 5-HT₄ receptors have a broad tissue distribution with important roles in both the CNS and the periphery [269–272]. In the brain, 5-HT₄ receptors are localized postsynaptically on neurons and may mediate slow excitatory responses to 5-HT (Fig. 8.3). In collicular and hippocampal neurons, 5-HT₄ receptors stimulate adenylyl cyclase and an inhibition of K⁺ channels mediated by the activation of cAMP-dependent protein kinase [273]. Peripherally, 5-HT₄ receptors facilitate acetylcholine release in guinea pig ileum and may play a role in the peristaltic reflex [269]. Consequently, 5-HT₄ receptors have been implicated in a variety of pathological disorders; in particular, 5-HT₄ receptor agonists show efficacy in the treatment of irritable bowel syndrome [274] (Table 8.1). In addition, 5-HT₄ receptor agonists have shown promise in the improvement of cognitive function by enhancing cholinergic transmission in the hippocampus [1, 275, 276]. As such, 5-HT₄ receptors may be involved in memory and learning and have been shown to be markedly decreased in patients with Alzheimer's disease [113, 277].

8.3.6 5-HT₅ Receptor Family

The 5-HT₅ receptor family is a poorly understood class of 5-HT receptors that consists of two members designated as 5-HT_{5A} and 5-HT_{5B}. Interestingly, only the 5-HT_{5A} receptor is expressed in humans as the 5-HT_{5B} receptor coding sequence is interrupted by stop codons [278, 279]. Both the 5-HT_{5A} and 5-HT_{5B} receptors are, however, expressed in mouse and rat [280–283]. The 5-HT₅ receptors exhibit less than 50% amino acid sequence homology with other 5-HT receptors, suggesting that they represented a distinct family of receptors and early attempts failed to demonstrate G-protein coupling [280–283] (Fig. 8.3). However, subsequent studies have shown that 5-HT_{5A} receptors can signal via G α_i /G α_o proteins and the inhibition of adenylyl cyclase in heterologous expression systems [284]. Interestingly, 5-HT_{5A} receptors also appear to be coupled to the inhibition of adenosine diphosphate (ADP)–ribosyl cyclase and the activation of phospholipase C, suggesting a complex crosstalk between multiple signal transduction pathways [285, 286]. In situ hybridization studies demonstrated a low-level but widespread distribution of 5-HT_{5A} receptor mRNA in neuronal cells in both mouse and rat brain [280, 282]. It appears, however, that the primary site of 5-HT_{5A} receptor expression is nonneuronal [284].

The pharmacological function of 5-HT_{5A} receptors is currently unknown though it has been speculated that, on the basis of their localization, they may be involved in motor control, feeding, anxiety, depression, learning, memory consolidation, adaptive behavior, and brain development [278, 281, 283] (Table 8.1). The 5-HT_{5A} receptors may also be involved in a neuronally driven mechanism for regulating astrocyte physiology, with relevance to gliosis, and thus may play a role in the pathophysiology of diseases such as Alzheimer's disease [284]. A 5-HT_{5A} receptor knockout mouse line has been made with minimal phenotypic changes observed to date [287]. These mice do, however, display increased locomotor activity and

exploratory behavior, though there was no difference in the anxietylike behavior of these animals in the elevated plus maze paradigm [287].

8.3.7 5-HT₆ Receptors

The 5-HT₆ receptor was initially detected by two groups following identification of a cDNA sequence which encoded a 5-HT-sensitive receptor with a novel pharmacology [288, 289] and was followed by the cloning human 5-HT₆ receptor [291]. The 5-HT₆ receptor can be radiolabeled with [¹²⁵I]LSD and couples to the stimulation of adenylyl cyclase [288, 289]. The 5-HT₆ receptor mRNA appears largely confined to the CNS, though low levels have been detected in the stomach and adrenal glands [288, 289]. Within the brain, high levels of 5-HT₆ receptor mRNA are found in the striatum, nucleus accumbens, and hippocampus [288–292]. By immunohistochemistry, 5-HT₆ receptor-like immunoreactivity was abundant in similar regions as the 5-HT₆ receptor mRNA (striatum, nucleus accumbens, hippocampus, and cerebral cortex), suggesting that the receptor protein is expressed in close proximity to the site of synthesis [291]. Further studies revealed that 5-HT₆ receptors are predominantly postsynaptic to serotonergic neurons and are not autoreceptors [291–294] (Fig. 8.3).

The distribution of the 5-HT₆ receptor as well as its high affinity for a number of antipsychotics, including clozapine and loxapine, and some tricyclic antidepressants such as amoxipine, amitriptyline, and clomipramine [288, 295, 296] has led to significant efforts to understand its possible role in psychiatry. The first behavioral studies of 5-HT₆ receptor function used antisense oligonucleotides to decrease the level of 5-HT₆ receptor expression [297]. In these studies, rats exhibited an increased number of yawns and stretches that could be blocked by atropine, suggesting a role of the 5-HT₆ receptor in the control of cholinergic neurotransmission [298, 299]. Thus, 5-HT₆ antagonists may have a role in the treatment of cognitive dysfunction such as in Alzheimer's disease [1, 300]. Indeed, the selective 5-HT₆ antagonist SB-271046 has been shown to improve memory retention in the water maze test of spatial learning and memory [299, 301] (Table 8.1). The 5-HT₆ receptors also appear to have a role in anxiety as a reduction in 5-HT₆ receptor levels by antisense oligonucleotides suppressed 5-HT release in a conditioned fear stress paradigm [302]. In addition, a 5-HT₆ knockout mouse demonstrated a reduced response to the acute effects of ethanol [303]. It is important to point out, however, that 5-HT₆ receptor knockout mice may be of limited utility as the levels of 5-HT₆ receptor expression in mice is very low and there are significant pharmacological differences between the mouse 5-HT₆ receptor and the rat and human receptors [304, 305]. It appears likely, though, that 5-HT₆ receptors will have an important future role in the treatment of neuropsychiatry illnesses—especially in terms of enhancing cognition.

8.3.8 5-HT₇ Receptors

In 1993, the 5-HT₇ receptor was cloned independently by researchers in four laboratories [306–309]. This G-protein-coupled receptor protein was found to be positively coupled to adenylyl cyclase through G α_s [306–309]. The 5-HT₇ receptor mRNA was found in the brain, mainly in the hypothalamus, thalamus, hippocampus, and cortex, and in the periphery, mainly in blood vessels and the intestines [306–309]. At least three different splice variants of the 5-HT₇ receptor have been identified in rat

and human tissues, though the functional role of these splice variants is still unknown [310–312]. It is possible that since these variants differ in the length of their C-terminal tails and in the number of phosphorylation sites, they are likely to have functional differences in their susceptibility to desensitize and the efficiency of G-protein coupling.

The 5-HT₇ receptor exhibits a distinct distribution in the CNS with both mRNA and receptor binding sites displaying a similar pattern of distribution with relatively high levels in the thalamus, hypothalamus, and hippocampus and lower levels in the cortex and amygdala [313–316]. Significant tissue-specific differences in the distribution of 5-HT₇ receptor splice variants is not apparent [310, 311, 317], though the overall abundance of individual isoforms differs among species [310, 311, 317]. A low level of expression of 5-HT₇ receptors has been detected in the periphery, especially in the smooth muscle of blood vessels [318, 319].

Recent studies suggest that the 5-HT₇ receptor is involved in thermoregulation, circadian rhythm, learning and memory, hippocampal signaling, sleep, and endocrine regulation. For example, in rat hippocampal slices, 8-OH-DPAT induced a phase resetting within the suprachiasmatic nucleus (a region important in the regulation of circadian rhythms) that was shown to be mediated by the 5-HT₇ receptor [308, 320–323]. In addition, selective 5-HT₇ receptor antagonists administered to rats at the beginning of the sleep phase increased the latency to rapid eye movement (REM) sleep and decreased the amount of time spent in REM sleep [324], changes that are directly opposite of the sleep patterns seen in depressed patients. Several antipsychotics and antidepressants have high affinities for the 5-HT₇ receptor [289, 296], and antidepressants may exert some of their function through the 5-HT₇ receptors [325]. These findings are compatible with the hypothesis that the 5-HT₇ receptor is of considerable importance for regulating sleep, circadian rhythms, and mood.

The 5-HT₇ receptor has also been shown to have an important role in hippocampus-dependent functions such as learning and memory [326]. For example, 5-HT₇ receptor knockout mice have been found to exhibit a specific impairment in contextual fear conditioning in which the animal learns to associate the environment with an aversive stimulus and is generally believed to depend on the hippocampus [327]. There was no difference, however, between wild-type and knockout mice in the Barnes maze test, in which the mouse must learn how to escape an open area by locating a chamber using environmental cues [327]. Electrophysiological studies have shown that 5-HT₇ receptor activation decreased the amplitude of slow afterhyperpolarizations in the CA3 region of the hippocampus by inhibiting Ca²⁺-activated K⁺ channels [50a] and to modulate the excitability and intracellular signaling of pyramidal neurons in the CA1 region of the hippocampus [328, 329]. In addition, in 5-HT₇ receptor knockout mice, there is a reduced ability to induce long-term potentiation in the CA1 region of the hippocampus [327]. These findings together suggest an important role for the 5-HT₇ receptor in hippocampus-dependent functions, including learning and memory [326]. Thus, selective 5-HT₇ receptor ligands might prove therapeutically useful for the treatment of a number of neuropsychiatric disorders (Table 8.1).

8.4 FUTURE OF 5-HT RESEARCH

As has been demonstrated, the 5-HT system has been implicated in many CNS functions [1, 2], owing to the vast coverage of serotonergic projections from the raphe

nuclei throughout the CNS, the large catalog of 5-HT receptor subtypes, and their differential cellular distribution. This enormous range of actions of the 5-HT system suggests a predominantly neuromodulatory role for 5-HT in the CNS. Further highlighting the importance of the 5-HT system is the fact that the mechanism of action of most drugs currently in use for the treatment of psychiatric disorders (e.g., depression, schizophrenia, anxiety disorders, obsessive-compulsive disorder) is thought to be mediated at least in part via the 5-HT system. Thus, it is not surprising that 5-HT receptors and transporters continue to be a major focus of CNS drug discovery [2]. Advances in molecular and cellular research on individual receptor subtypes have provided new experimental tools, such as ligands with greater receptor selectivity and gene knockouts, which will allow for more sophisticated behavioral analysis of the 5-HT system. Ultimately, the integration of these advances in our understanding of the complex actions of 5-HT mediated by the various receptor subtypes will help us precisely define the overall function of 5-HT in the CNS.

The early history of histamine started at the beginning of the twentieth century, was dominated by the works of great british pharmacologists, namely Henry Dale and W. Feldberg, and contributed to develop the common idea that this amine, ubiquitously present in a large variety of tissues (hence its name, derived from *histos*, Greek for "tissue"), was essentially playing a noxious role in the body. In agreement, the design and large therapeutic utilization of two classes of histamine receptor antagonists, the H₁ receptor antagonists by Bovet and colleagues in France [1] and the H₂ receptor antagonists by Black and colleagues in the United Kingdom [2], have allowed to alleviate in millions of patients the harmful actions of the amine when released from its two main cellular stores in peripheral tissues, that is, the mast cells and gastric enterochromaffin-like cells, respectively.

The idea that histamine may have a useful function as a neurotransmitter in brain emerged only slowly during the preceding century, essentially at the beginning of the 1970s [3], although it had been detected therein much earlier [4]. The main landmarks in this history can be summarized as follows. The development of reliable and sensitive methods to assay the amine and its synthesizing enzyme [5, 6] was instrumental in allowing to establish its cellular and subcellular localization in neurons as well as its presence in a neural pathway traveling in the medial forebrain bundle, as evidenced indirectly by lesion studies [7]. In contrast with the amine in peripheral mast cells, the turnover of the amine in cerebral neurons was found to be rapid and almost instantaneously modified by drugs such as barbiturates and reserpine [8–10]. The demonstration of depolarization-induced release and enhanced synthesis via calcium-dependent mechanisms [11–13], the elucidation of inactivating metabolic pathways [14, 15], and the characterization in brain of the H₁ and H₂ receptors by biochemical and electrophysiological approaches [16, 17] completed by the mid-1970s the "picture" of histamine as a typical monoaminergic neurotransmitter. Even more, taking into account a variety of features of the system made available at this time, it was proposed that histaminergic neurons were critically involved in the control of arousal [18].

Nevertheless it took nearly 10 years to develop reliable immunohistochemical tools which permitted to identify a tiny posterior hypothalamic area, the tuberomammillary nucleus, as the origin of the histaminergic pathways [19, 20] and, thereby, fully convince the neurobiological community of their existence: “Seeing is believing.” At approximately the same time, the third histamine receptor was identified in our laboratory, almost exclusively present in brain, where it controls the neurotransmitter release and synthesis [21], and the first selective and brain-penetrating ligands were developed [22]; these agents were used, thereafter, in hundreds of studies to modify the activity of histaminergic neurons and thereby disclose their functions.

These basic aspects, as briefly summarized above, were covered in detail in a comprehensive review [23] and will not be repeated in this chapter, which is centered on more recent studies leading to therapeutic perspectives. Other reviews on the neurobiology and pharmacology of histamine in brain have also appeared more recently [24–26].

9.1 ORGANIZATION OF HISTAMINERGIC NEURONAL SYSTEM

9.1.1 Histaminergic Perikarya

One decade after the first evidence by Garbarg et al. of an ascending histaminergic pathway obtained by lesions of the medial forebrain bundle [7], the exact localization of corresponding perikarya in the posterior hypothalamus was revealed immunohistochemically in the rat using antibodies against histamine [19] or L-histidine decarboxylase (EC 4.1.1.22, HDC), the enzyme responsible for the one-step histamine formation in the brain [27]. Data on the distribution, morphology, and connections of histamine and HDC-immunoreactive neurons were comprehensively reviewed [23, 28–31] and will be only summarized briefly here.

All known histaminergic perikarya constitute a continuous group of mainly magnocellular neurons located in the posterior hypothalamus and collectively named the tuberomammillary nucleus (Fig. 9.1). This anatomical position was observed in all mammals studied so far and in other vertebrates, including fish, reptiles, and amphibians [31], indicating that the histaminergic system is phylogenetically old and has been well preserved through the evolution. In invertebrates, histamine-immunoreactive neurons were visualized not only in the brain of molluscs [32, 33] and insects [34–36] but also in the visual system of insects [34–36], where histamine is the neurotransmitter in retinal photoreceptors, as shown by the impairment of visual behavior in HDC-deficient *Drosophila* mutants [37, 38]. The histamine-like immunoreactivity observed in photoreceptors of the turtle retina [39] and the presence of HDC-immunoreactive neurons in the guinea pig retina [40] may also indicate that histamine plays some role in the retina of vertebrates. In the rat brain, the tuberomammillary nucleus consists of about 2000 histaminergic neurons [41] and can be subdivided into medial, ventral, and diffuse subgroups extending longitudinally from the caudal end of the hypothalamus to the midportion of the third ventricle. A similar organization was described in humans, except that histaminergic neurons are more numerous (~64,000) and occupy a larger proportion of the hypothalamus [42]. Besides their large size (25–35 μm), tuberomammillary neurons

Figure 9.1 Localization of histaminergic perikarya in tuberomammillary nucleus. (a–c) Histaminergic perikarya are represented by closed circles on frontal sections at indicated levels of caudal hypothalamus. (d) Histidine decarboxylase (HDC) mRNA expression (left) and immunoreactivity (right) in ventral tuberomammillary subgroup (rostral part). Abbreviations: Arc, arcuate nucleus; cmc, caudal magnocellular nucleus; MM, medial mammillary nucleus medial part; MMn, medial mammillary nucleus median part; MP, medial mammillary nucleus posterior part; pcmc, posterior caudal magnocellular nucleus; PMV, premammillary nucleus ventral part; SuM, supramammillary nucleus; TMC, tuberal magnocellular nucleus; TMdiff, tuberomammillary nucleus diffuse part; TMMd, medial tuberomammillary subgroup dorsal part; TMMv, medial tuberomammillary subgroup ventral part; TMVc, ventral tuberomammillary subgroup caudal part; TMVr, ventral tuberomammillary subgroup rostral part.) (See color insert.)

are characterized by few thick primary dendrites, with overlapping trees, displaying few axodendritic synaptic contacts. Another characteristic feature is the close contact of dendrites or fibers with the ventral surface of the mammillary bodies and the wall of the ventricles in a way suggesting that they penetrate through the ependymal cell layer to reach the cerebrospinal fluid, perhaps to secrete or receive still unidentified messengers [43, 44]. Neurons expressing messenger ribonucleic acids (mRNAs) for histidine decarboxylase were found by in situ hybridization in the tuberomammillary nucleus but not in any other brain area [45].

The histaminergic neurons are characterized by the presence of an unusually large variety of markers for other neurotransmitter systems. Most, if not all, contain γ -aminobutyric acid (GABA) [46, 47], which is stored in subcellular structures distinct from those containing histamine [48], and glutamic acid decarboxylase, the GABA-synthesizing enzyme [49, 50]. All histaminergic neurons also contain adenosine deaminase, a cytoplasmic enzyme possibly involved in adenosine inactivation [51, 52], and many express a splice variant of choline acetyltransferase [53]. Some histaminergic neurons also express several neuropeptides such as galanin, a peptide colocalized with all other monoamines [54], (Met⁵)enkephalyl-Arg⁶Phe⁷, a product of the proenkephalin A gene, substance P, thyroliberin, or brain natriuretic peptide [55]. However, these colocalizations are observed in various proportions and display

strong species differences [47, 56]. Tuberomammillary neurons also contain monoamine oxidase B, an enzyme responsible for deamination of *tele*-methylhistamine, a major histamine metabolite in brain. Finally a subpopulation of histaminergic neurons is able to uptake and decarboxylate exogenous 5-hydroxytryptophan, a compound that they do not synthesize, however [57, 58]. Unraveling the functions of such a high number of putative cotransmitters in the same neurons remains an exciting challenge.

9.1.2 Histaminergic Pathways

In analogy with other monoaminergic neurons, histaminergic neurons constitute long and highly divergent systems projecting in a diffuse manner to many cerebral areas [28–30] (Fig. 9.2). Immunoreactive, mostly unmyelinated, varicose or nonvaricose fibers are detected in almost all cerebral regions, particularly limbic structures. It was confirmed that individual neurons project to widely divergent areas. Histaminergic fibers mainly project in an ipsilateral fashion [7], but confocal imaging of whole zebra fish or young rodent brain confirmed that commissural fiber projections containing histamine connect the two hemispheres [31]. Ultrastructural studies suggest that histamine-immunoreactive fibers make few typical synaptic contacts.

Fibers arising from the tuberomammillary nucleus constitute two ascending pathways: one laterally, via the medial forebrain bundle, and the other periventricularly. These two pathways combine in the diagonal band of Broca to project to many telencephalic areas, for example, in all areas and layers of the cerebral cortex, the most abundant projections being to the external layers. Other major areas of termination of these long ascending connections are the olfactory bulb, the hippocampus, the nucleus accumbens, the globus pallidus, the thalamus, and the amygdaloid complex. Many hypothalamic nuclei exhibit a very dense innervation, for example, the suprachiasmatic, supraoptic, arcuate, or ventromedial nuclei. A histaminergic neuronal system reminiscent of that described in rodents is present in the monkey and human brain with, for example, a dense network of fibers present in various cortical areas [59, 60] or thalamic nuclei [61], such as those belonging to the ascending visual pathways [62].

Finally, a long descending histaminergic subsystem arises also from the tuberomammillary nucleus to project to a variety of mesencephalic and brain stem structures such as the cranial nerve nuclei (e.g., the trigeminal nerve nucleus), the central gray, the colliculi, the substantia nigra, the locus ceruleus, the mesopontine tegmentum, the dorsal raphe nucleus, the cerebellum (sparse innervation), and the spinal cord.

During development, histamine is transiently present between Ed14 and Ed18 in the raphe nucleus, a neuronal system that has completely disappeared by Ed20 [63]. In the tuberomammillary nucleus, histaminergic neurons express *hdc* mRNAs from Ed14 [64] and become HDC and histamine immunoreactive from Ed16 and Ed20, respectively, whereas the development of most fibers takes place during the first two postnatal weeks [65, 66].

9.1.3 Afferents to Histaminergic Neurons

Several anterograde and retrograde tracing studies established the existence of afferent connections to the histaminergic perikarya, namely from the infralimbic

cortex, the septum–diagonal band complex, the preoptic region, the hypothalamus, and the hippocampal area (subiculum) [30, 67]. Immunoelectron microscopic studies showed that substance P and neuropeptide Y afferents make direct synaptic contacts with histaminergic neurons [68, 69]. Sleep-active GABAergic neurons in the ventrolateral preoptic nucleus (VLPO) provide a major input to the tuberomammillary nucleus [70, 71]. The contacts between these two systems are reciprocal, because the VLPO is densely innervated by histaminergic fibers [72]. Histaminergic neurons also receive very dense orexin innervation originating from the lateral hypothalamus [73]. The ultrastructure of these orexin nerve terminals confirmed direct synaptic interactions and revealed that they also contain a glutamate immunoreactivity [74, 75]. Again, the relationships between the orexin and histamine systems seem to be reciprocal, because the orexin neurons are heavily innervated by histaminergic axons [76]. The same architecture of this neuronal loop is observed in zebrafish, indicating that it is conserved in vertebrates [77]. Supporting their role in the regulation of food intake, histaminergic neurons in all subgroups of the tuberomammillary nucleus are densely innervated by nerve fiber varicosities immunoreactive for amylin- and α -melanocyte-stimulating hormone, two anorexigenic peptides [78, 79]. Electrophysiological studies provided evidence for inhibitory and excitatory synaptic control of tuberomammillary neuron activity by afferents from the diagonal band of Broca, the lateral preoptic area, and the anterior lateral hypothalamic area [80]. Projections from the brain stem to the tuberomammillary nucleus have also been demonstrated. Retrograde tracing studies combined with immunohistochemistry showed that monoaminergic inputs to the tuberomammillary nucleus originate mainly from the ventrolateral and dorsomedial medulla oblongata and from the raphe nuclei, with a lower innervation originating from the locus ceruleus, the ventral tegmental area, and the substantia nigra [81, 82].

9.2 METABOLISM OF HISTAMINE

9.2.1 Biosynthesis

Histamine biosynthesis in the brain involves two steps: transport of the precursor L-histidine (His) into the cell and its subsequent decarboxylation by HDC [23]. Saturable, energy-dependent His uptake occurs in brain slices and synaptosomes and is stimulated by their depolarization.

The human HDC gene is composed of 12 exons spanning ~24 kb. Its transcripts are alternatively spliced but only the 2.4-kb mRNA, which is predominant in human brain, encodes functional HDC [83]. The native HDC is a pyridoxal phosphate-dependent enzyme under an homodimeric form constituted of two subunits of a 54-kDa isoform and mainly found in the cytoplasm of histaminergic neurons. The primary translation product is an inactive 74-kDa isoform [84, 85], which may account for membrane-bound HDC [86, 87] and is processed at its C-terminus to give rise to the active 54-kDa enzyme [88]. The K_m of brain HDC for His is ~0.1 mM [6, 89], a value presumably close to the intraneuronal concentration of the amino acid and which accounts for the enhanced brain histamine formation induced in vivo by histidine loads. The regional distribution of brain HDC activity is consistent with data derived from immunohistochemistry, with the highest activity being found in

the hypothalamus, the lowest levels in the cerebellum, and intermediate activity in telencephalic areas [6, 23]. α -Fluoromethylhistidine (α -FMH) is a specific and irreversible inhibitor of HDC [90]. Because it easily enters the brain and efficiently depletes histamine stores in cerebral neurons, the drug is useful for investigating the amine turnover and functions therein [91, 92]. HDC knockout mice also provide a suitable model to investigate the involvement of histaminergic neurons in the regulation of fundamental functions such as sleep–wake control [93], energy homeostasis [94], learning [95], seizure development [96], motor and emotional behaviors [97, 98], and circadian rhythms [99].

In neurons, the newly synthesized histamine is transported to vesicles by the vesicular monoamine transporter 2 (VMAT2) for which it displays high affinity [100]. VMAT2 gene transcripts have been detected in the tuberomammillary nucleus [101] and VMAT2 immunoreactivity could be visualized in most histamine-containing vesicles [48].

Although histaminergic neurons constitute the major localization of HDC, at least two other types of histamine-producing cells, mast cells and microglial cells, have been reported by lesion, biochemical, and histochemical studies. Mast cells contain only a small fraction of the cerebral HDC activity but a significant fraction (up to $\sim 50\%$) of the overall brain histamine content, indicating a slow histamine turnover in this pool. Although they are rather scarce in the brain, mast cells are generally abundant in leptomeninges and also occur in the parenchyma of various brain areas, such as thalamus, where they are mainly distributed along cerebral vessels [23]. The relatively high histamine level and low HDC content found in isolated cerebral microvessels or primary cultures of cerebral microvascular endothelial cells [23, 102] may also be due to occasional histamine-containing perivascular mast cells because histamine and HDC could not be detected in endothelial cells of adult rat brain [103]. Besides neurons and mast cells, microglial cells which belong to the monocyte/macrophage lineage, contain both HDC activity and mRNAs [104]. These cells are likely to be the site of HDC activation induced by lipopolysaccharide and interleukin- 1β in cultured cells of the rat embryonic brain [105] and could be responsible for the activation of the neuronal histaminergic system in the hypothalamus [106–108].

9.2.2 Inactivation

Brain histamine is metabolized via transmethylation into *tele*-methylhistamine (*t*-MeHA) catalyzed by histamine *N*-methyltransferase (HMT, EC 2.1.1.8) [23]. In vivo inhibition of HMT leads to an increase in neuronal histamine release, confirming that this enzyme plays a critical role in histamine inactivation [109], and HMT inhibitors such as metoprine are useful drugs to investigate the histamine functions in the brain [110, 111]. HMT may be an important target to modulate histaminergic neurotransmission in neuropsychiatric disorders. Its levels are decreased in Down syndrome and increased in Pick's disease [112], and the drug tacrine, which is used in long-term palliative treatment of Alzheimer's disease, inhibits HMT even more potently than acetylcholinesterase [113]. Among the various HMT polymorphisms that have been identified in the human gene [114–116], a common C314T transition located in exon 4 resulted in decreased levels of enzyme activity [117, 118] and was associated with asthma [119] and alcoholism [120] but not with schizophrenia [121]. Although evidence for a membrane-bound HMT was reported in mouse brain [122], subcellular

fractionation studies have shown brain HMT to be mainly a soluble enzyme [23]. HMT-like immunoreactivity within the CNS was found in the cytosol of a variety of neurons and in vascular walls, whereas astrocytes were not stained [123].

How extracellular histamine is transported into these HMT-containing cells is still unclear. In contrast with other monoaminergic systems, no clear evidence for a high-affinity uptake system for histamine could be found [23]. Nevertheless, the poly-specific organic cation transporters OCT2 and OCT3 may play an important role in histamine inactivation [124]. OCT2, a “background” transporter involved in the removal of monoamine neurotransmitters, is expressed in neurons of various rat and human brain areas and mediates low-affinity transport of histamine as well as catecholamines and serotonin [125, 126]. Histamine is also a good substrate for OCT3, which was identified as the major component of the extraneuronal monoamine transport system (EMT or uptake 2) previously characterized mainly in peripheral tissues [127]. In situ hybridization revealed that OCT3 is widely distributed in different brain regions, with a prominent neuronal expression detected in cerebral cortex, hippocampus, cerebellum, and pontine nucleus [128]. Because they display a wide distribution, OCT2 and OCT3 might account at least partly for the uptake of labeled histamine reported in brain slices [129, 130].

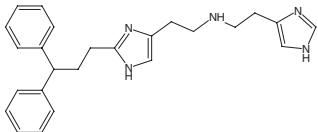

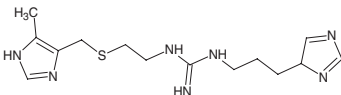

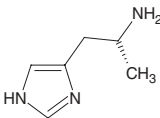

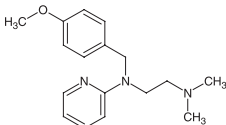

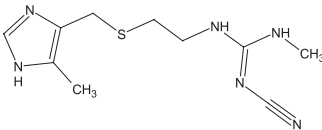

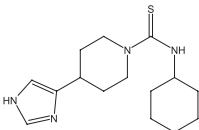

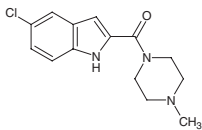

9.3 MOLECULAR PHARMACOLOGY AND LOCALIZATION OF HISTAMINE RECEPTOR SUBTYPES

In the brain, the effects of histamine are mediated by three histamine receptor subtypes (H_1 , H_2 , and H_3), which have been defined by means of functional assays followed by design of selective agonists and antagonists and, more recently, cloning of their genes [131, 132]. All three belong to the superfamily of receptors with seven transmembrane domains and coupled to guanylnucleotide-sensitive G proteins (Table 9.1). Some effects of histamine are also mediated by ionotropic receptors. Histamine directly interacts with an allosteric site of the glutamatergic *N*-methyl-D-aspartate (NMDA) receptor. At photoreceptor synapses in the insect eye, histamine activates histamine-gated chloride channels [133–135] which may also exist in the brain of vertebrates [136].

9.3.1 Histamine H_1 Receptor

9.3.1.1 Molecular Properties. The H_1 receptor was initially defined in functional assays (e.g., smooth muscle contraction) and the design of potent antagonists, the so-called antihistamines (e.g., mepyramine), most of which display prominent sedative properties. It was first cloned from cow by expression cloning [137] and subsequently from a variety of species, including man [131]. The human gene contains an intron in the 5'-flanking untranslated region, close to the translation initiation codon, but the translated region is intronless [138]. Several polymorphisms have been identified in the promoter and coding region of the H_1 receptor gene, but none of them was found to be associated with schizophrenia or response to clozapine [139–142]. Recently, the H_1 receptor was identified in the mouse as the general autoimmunity locus *Bphs*, and three polymorphisms leading to amino acid changes at positions 263, 313, and 331 in the third intracellular loop were shown to be associated with susceptibility to

TABLE 9.1 Properties of Four Histamine Receptor Subtypes^a

Property	H ₁	H ₂	H ₃	H ₄
Coding sequence	491 a.a. (b) 488 a.a. (gp) 486 a.a. (r)	358 a.a. (r) 359 a.a. (d, h, gp)	445 a.a. (h) Shorter variants (h, r, m, gp)	390 a.a. (h) 389 a.a. (gp) 391 a.a. (m, r)
Chromosome localization	3p25	5	20qTEL	18q11.2
Highest brain densities	Thalamus, cerebellum, hippocampus	Striatum, cerebral cortex, amygdala	Striatum, frontal cortex, substantia nigra	Very low density
Autoreceptor	No	No	Yes	No
Affinity for histamine	Micromolar	Micromolar	Nanomolar	Nanomolar
Characteristic agonists	<i>N</i> ^α -[2-(1 <i>H</i> -imidazol-4-yl)ethyl]histaprodifen 	Impromidine 	<i>R</i> - α -methylhistamine 	—
Characteristic antagonists	Mepyramine 	Cimetidine 	Thioperamide 	JNJ 777120 
Radioligands	[³ H]Mepyramine, [¹²⁵ I]iodobolpyramine	[³ H]Tiotidine, [¹²⁵ I]iodoaminopotentidine	[³ H] <i>R</i> - α -Methylhistamine, [¹²⁵ I]iodoproxyfan	[³ H]Histamine
Second messengers	Inositol phosphates (+), Ca ²⁺ (+), arachidonic acid (+), cAMP (potentiation)	cAMP (+), Ca ²⁺ (+)	cAMP (–), inositol phosphates (–), arachidonic acid (+), Ca ²⁺ (–)	cAMP (–)

multiple autoimmune diseases such as experimental allergic encephalomyelitis (EAE) [143]. The marked species differences in H₁ receptor pharmacology that have been reported result from differences in binding pockets and conformational flexibility of the proteins [23, 144, 145].

9.3.1.2 Signaling. The histamine H₁ receptor produces its intracellular effects via the activation of G_{q/11} proteins [131, 146] (Fig. 9.3). Various intracellular responses were found to be mediated by stimulation of recombinant H₁ receptors or native H₁ receptors present in brain tissues and various cell systems [23, 147]. H₁ receptor activation leads to stimulation of phospholipase C β and inositol phosphate release. The subsequent mobilization of Ca²⁺ from intracellular stores followed by an influx of extracellular Ca²⁺ induces an increase in intracellular Ca²⁺ levels which was observed in transfected fibroblasts [147], neurons [148], and glial cells [149–151]. This process is presumably responsible for the activation of various Ca²⁺-dependent pathways by the recombinant or native H₁ receptor, such as potentiation of cyclic adenosine monophosphate (cAMP) accumulation, cyclic guanosine monophosphate (cGMP) accumulation, arachidonic acid release, and glycogenolysis [23, 147]. Potentiation of H₂ receptor-mediated cAMP accumulation via H₁ receptor stimulation accounts for an enhanced response to histamine in neurons coexpressing the H₁ and H₂ receptors [152].

In vasopressinergic neurons of the rat supraoptic nucleus, nitric oxide synthase activation mediated by H₁ receptors induces cGMP accumulation that results in increased interneuronal coupling [153]. Via stimulation of phospholipase C β and subsequent activation of protein kinase C α , the H₁ receptor can also signal to the nucleus and induces *c-fos* expression in CHO-transfected cells [154] or hypothalamic neurons [155, 156].

Constitutive activity of the recombinant H₁ receptor could be evidenced on several signaling pathways [157–159]. Several H₁ receptor antagonists behaved as inverse agonists, that is, reduced this constitutive activity, but the physiological relevance of the process, for example, in brain, remains doubtful [160].

9.3.1.3 Responses in Brain Tissues. The H₁ receptor mediates mainly excitatory responses in brain, leading to a depolarization and/or an increase in firing frequency in many neurons [24, 25]. A reduction of a background leakage potassium current induces excitation of cortical, striatal, and lateral geniculate relay neurons [161–163]. Activation of a tetrodotoxin-insensitive sodium current depolarizes cholinergic septal neurons [164]. The increase in intracellular Ca²⁺ levels mediated by the H₁ receptor activates a Ca²⁺-activated cation current or a Ca²⁺/Na⁺ pump that depolarizes supraoptic neurons [165] and enhances depolarizing afterpotentials, leading to an increase in firing of the same neurons [166, 167]. Stimulation of the H₁ receptor enhances the firing of serotonergic dorsal raphe neurons via activation of a mixed cation channel [168, 169]. The H₁ receptor facilitates the NMDA-mediated depolarization of cortical neurons presumably via protein kinase C (PKC) activation [170].

H₁ receptor activation also increases firing of cholinergic nucleus basalis neurons [171] and of GABAergic neurons in the substantia nigra and ventral tegmental area [172]. Hyperpolarizations or depressions of firing mediated by H₁ receptors have occasionally been observed in some neurons such as hippocampal pyramidal cells [173] or olfactory bulb neurons [174]. They mainly result from activation of a

Abbreviations: AA, arachidonic acid; AC, adenylate cyclase; DA, dopamine; ERK, extracellular signal-related kinase; GABA, γ -aminobutyric acid; GC, guanylate cyclase; Glu, glutamate; IP₃, inositol-1,4,5-triphosphate; NA, noradrenaline; PKA, protein kinase A; PLA₂, phospholipase A₂; PLC, phospholipase C; NO, nitric oxide. (See color insert.)

Ca^{2+} -activated potassium conductance via release of calcium from intracellular stores [151]. The suppression of non-NMDA excitatory synaptic currents in supraoptic neurons may rather result from the production of nitric oxide [175]. H_1 receptors inhibit high-frequency (“ripple”) network oscillations in the hippocampal CA1 area via an unknown mechanism [176, 177].

In agreement with the in vitro electrophysiology, in vivo microdialysis studies show that activation of H_1 receptors in the nucleus basalis magnocellularis increases cortical acetylcholine release [178] and stimulation of H_1 receptors enhances acetylcholine release in the ventral striatum [179]. Microdialysis studies also show that activation of H_1 receptors increases noradrenaline release in the hypothalamus [180]. The increase in dopamine release induced by some H_1 receptor antagonists in the striatum presumably results from the blockade of dopamine uptake and may explain the abuse potential of such compounds [181]. In agreement, dopamine turnover remains unchanged in the forebrain from H_1 receptor knockout mice [182].

9.3.1.4 Distribution. Biochemical and localization studies of the H_1 receptor were made feasible with the design of reversible and irreversible radiolabeled probes such as [^3H]mepyramine, [^{125}I]iodobolpyramine, and [^{125}I]iodoazidophenpyramine [183, 184]. At the cellular level, although H_1 receptors are present on glial [149, 150, 185, 186] and cerebral endothelial cells [103, 187], their distribution in the brain is consistent with a predominant neuronal localization. H_1 receptor distribution in the guinea pig brain was established autoradiographically using [^3H]mepyramine or the more sensitive probe [^{125}I]iodobolpyramine [188] (Fig. 9.2) and the information complemented by in situ hybridization of the mRNA [189]. For instance, the high density of H_1 receptors in the molecular layers of cerebellum and hippocampus seems to correspond to dendrites of Purkinje and pyramidal cells, respectively, in which the mRNA is highly expressed. H_1 receptor binding sites are also abundant in guinea pig thalamus, hypothalamic nuclei (e.g., ventromedial nuclei), nucleus accumbens, amygdaloid nuclei, and frontal cortex but not in neostriatum [184]. Autoradiographic studies in the fish brain show that H_1 receptors are also localized primarily in the cerebellum and the thalamus [190]. In the human brain, binding sites are more abundant in the neostriatum than in the guinea pig [191] and, in agreement with the H_1 receptor-mediated modulation of thalamocortical functions by histamine, H_1 receptor binding sites and mRNAs are abundant in the human thalamus and prefrontal cortex [61, 192].

H_1 receptor mRNAs could be detected in rat brain from Ed14 [193], and the developmental profile of mRNAs and binding sites during the first two postnatal weeks, although not strictly parallel, is well correlated with that of histaminergic innervation [193–195]. Age-related decreases in H_1 receptors have been found in the mouse and human brain and may contribute to diminished alertness in aging [196, 197].

H_1 receptors were visualized and quantified in the primate and human brain in vivo by positron emission tomography (PET) using [^{11}C]mepyramine or [^{11}C]doxepin [198]. PET studies revealed a significant decrease in H_1 receptor binding in the brain of patients with Alzheimer’s disease [199] and of depressed or schizophrenic patients [200, 201].

Blockade of H₁ receptors in brain is presumably involved in the sedative (Section 9.5.1), pro-obesity (Section 9.5.4), and proconvulsant (Section 9.5.5) properties of many psychotropic drugs displaying high H₁ receptor affinity.

H₁ receptor knockout mice have been generated to further investigate the involvement of H₁ receptors in various neurochemical and behavioral responses. An increase in the turnover rate of serotonin was found in the mutant mice [182]. The behavioral data obtained with the knockout mice largely confirm the previous pharmacological findings and support a role of H₁ receptors in arousal and cognition [202–204], anxiety and aggressive behavior [182], nociception [205, 206], anticonvulsant action [96, 207], and regulation of food intake and body weight [208, 209].

9.3.2 Histamine H₂ Receptor

9.3.2.1 Molecular Properties and Signaling. Studies of the molecular properties of the H₂ receptor have been greatly facilitated in the 1990s by the design of its first potent and selective radioligand, [¹²⁵I]iodoaminopotentidine [210, 211], as well as by the cloning of its gene in various species, including man [131, 212, 213].

The 5'-untranslated region of the human gene contains an intron but the translated region is intronless [213, 214]. Although none of the six polymorphisms of the coding region initially reported in a U.K. population could be detected in other studies, several polymorphisms have been identified in various ethnic groups in the promoter region, and one (543G/A) in the coding region, of the H₂ receptor gene, but none were found to be associated with schizophrenia or response to clozapine [139, 140, 142, 215–217].

The recombinant or native H₂ receptor is coupled to G_s proteins and mediates activation of adenylyl cyclase with subsequent increases in cAMP formation and protein kinase A activation [23, 131, 218, 219] (Fig. 9.3). This pathway may mediate the H₂ receptor-induced ERK2 activation observed in vitro in hippocampal CA3 cells [220]. In the brain, the cAMP response mediated by H₂ receptors occurs predominantly in neurons, but it was also evidenced in astrocytes [221], epithelial cells of choroid plexus [222], and microvessel-enriched preparations [223]. Recombinant H₂ receptors also activate cAMP-independent signaling pathways and induce an increase in inositol phosphate release and intracellular Ca²⁺ concentration [224], a PKC-dependent *c-fos* activation [225], and a PKA- and PKC-independent *c-jun* activation [226]. An inhibition of arachidonate release was reported after activation of the recombinant rat receptor [227] but was not observed after activation of the human receptor [228]. Whether these various responses, which are either opposite or similar to those evoked by H₁ receptor stimulation, are activated in the brain remains unknown.

The recombinant H₂ receptor exhibits constitutive activity and several H₂ receptor antagonists behave as inverse agonists on cAMP formation [229–231]. However, constitutive activity of the native H₂ receptor in brain was not substantiated [160].

9.3.2.2 Responses in Brain Tissues. As the H₁ receptor, the H₂ receptor usually mediates excitatory responses in neurons [24, 25]. In hippocampal pyramidal neurons and granule cells of the dentate gyrus, H₂ receptor stimulation decreases a Ca²⁺-dependent K⁺ conductance through cAMP and PKA and reduces the accommodation of action potential firing, leading to an enhanced and long-lasting response

[232–235]. H_2 receptor activation depolarizes thalamic relay neurons by increasing membrane conductance, a response due to enhancement of the hyperpolarization-activated cation current I_h [162]. In striatal interneurons, H_2 receptors act synergistically with H_1 receptors to depolarize the cells via blockade of a leak potassium conductance [161]. H_2 receptor activation also increases the spontaneous firing of the alveus/oriens interneurons in the hippocampus [236], rubral neurons [237], medial vestibular nucleus neurons [238, 239], and cerebellar Purkinje and interpositus nuclear cells [240, 241]. In addition to these short-lasting effects, H_2 receptor activation also induces very long lasting increases in excitability in the CA1 region of the hippocampus, a process modulated by H_1 and NMDA receptors [173].

Depressions of firing mediated by H_2 receptor activation have also been reported in some neurons. The depressions of firing observed in several brain areas in the earlier single-unit and iontophoretic studies were most likely due to an excitation of GABAergic neurons [24]. However, in recent studies, H_2 receptor activation decreased neuronal excitability and coupling in oxytocin neurons of the supraoptic nucleus [136]. It inhibits GABAergic neurons of the thalamic perigeniculate nucleus through increases in membrane chloride conductance, a mechanism that may be involved in the transition from sleep to arousal [242]. H_2 receptor-mediated phosphorylation of voltage-gated potassium channels (Kv3.2) decreases the maximum firing frequency of hippocampal interneurons [243].

H_2 receptors that are not presynaptically located facilitate noradrenaline release from superfused guinea pig brain slices [244]. In vivo, activation of H_2 receptors enhances the release of acetylcholine in the ventral striatum [179], the medial septum–diagonal band complex [245], and the hippocampus [246, 247]. The systemic administration of zolantidine, the sole brain-penetrating H_2 receptor antagonist available [248], inhibits acetylcholine release, indicating its facilitation by endogenous histamine [246]. The decrease of ischemic release of dopamine and glutamate by H_2 receptor activation may be a contributing factor in alleviation of neuronal damage in the striatum [249].

9.3.2.3 Distribution. The H_2 receptor and/or its mRNA are detected on glial [250] and cerebral endothelial cells [103], but their distribution in the brain is consistent with a predominant neuronal localization. Autoradiographic localization of the H_2 receptor using [125 I]iodoaminopotentidine in the guinea pig [211, 251], monkey, and human brain [191, 210, 252] shows it distributed heterogeneously (Fig. 9.2). The H_2 receptor is found in most areas of the cerebral cortex, with the highest density in the external layers and the piriform and occipital cortices, the latter containing low H_1 receptor density. The caudate putamen, ventral striatal complex, and amygdaloid nuclei (bed nucleus of the stria terminalis) are among the richest brain areas. The distribution of the mRNAs is generally in agreement with that of the corresponding binding sites [192, 251, 252]. In the striatum, the absence of mRNAs in the substantia nigra and the loss of binding sites in Huntington's disease [253] indicate that H_2 receptors are expressed by intrinsic neurons. In the hippocampal formation, the relative localizations of the H_2 receptor and its gene transcripts are similar to that observed for the H_1 receptor: The gene transcripts are expressed in all pyramidal cells of Ammon's horn and in granule cells of the dentate gyrus, whereas the H_2 receptor is expressed in the molecular layers of these areas, which contain the dendritic trees of

the mRNA-containing neurons [251]. The partial overlap with the H_1 receptor may account for their synergistic interaction in cAMP accumulation. During development, H_2 receptors are transiently expressed at Ed15 together with histamine in the raphe nuclei and from Ed16 in several target areas for the histaminergic fibers [254]. mRNA levels do not change with age, except in the cerebellum, in which a significant increase has been found [197].

The brain-penetrating H_2 receptor antagonist zolantidine has been used to investigate the involvement of H_2 receptors in various neurochemical and behavioral responses [255, 256]. A rather limited number of data has also been obtained with H_2 receptor knockout mice, which tend to display a higher spontaneous locomotor activity and rearing behavior and lower susceptibility to electrically induced convulsions [257]. A number of tricyclic antidepressants are very potent inhibitors of the H_2 receptor-linked adenylylcyclase on brain membranes [258, 259] but not on intact cell preparations [260]. In addition, the idea that antidepressants derive their clinical efficacy from blockade of cerebral H_2 receptors seems unlikely because such a blockade was not observed after chronic treatments [261].

9.3.3 Histamine H_3 Receptor

9.3.3.1 Molecular Properties and Signaling. The H_3 receptor was initially detected and identified by traditional pharmacological approaches as an autoreceptor controlling histamine synthesis and release in the rat and human brain [21, 22, 262]. The recent cloning of its complementary deoxyribonucleic acids (cDNA) in various species including human and rat confirmed that the H_3 receptor is coupled to G_i/G_o proteins [263–265].

The H_3 receptor gene contains two introns in its coding sequence. These two introns, which are conserved in the human [266–268], rat [269], and mouse [270] H_3 receptor genes, are located in the second transmembrane domain and second intracellular loop, respectively. Several shorter isoforms generated by the deletion of a pseudointron in the third intracellular loop of the receptor are expressed in the brain from guinea pig [271], rat [263, 265, 269], mouse [270], and human [266, 267, 272]. The existence of these variants, which display a differential expression pattern and limited pharmacological differences, may account for the apparent H_3 receptor heterogeneity previously reported in binding or functional studies.

In addition to an isoform-related heterogeneity, H_3 receptors show a species-related heterogeneity. Although they show a high overall sequence homology, both the native [22, 262, 273, 274] and recombinant [275–278] rat and human H_3 receptors display distinct pharmacological properties, some antagonists/inverse agonists, such as thioperamide or ciproxifan, being more potent at the rat receptor, others being more potent at the human receptor. Using site-directed mutagenesis, two amino acids in the third transmembrane domain were found to be responsible for the pharmacological differences between the two species [276].

In various cell lines, activation of the recombinant H_3 receptor inhibits adenylyl cyclase [264], activates phospholipase A_2 [263], and activates the ERK signaling pathway [64, 265] (Fig. 9.3). The negative coupling of a native H_3 receptor to phospholipase C has been reported in a gastric tumor cell line [279]. However, whether any of these transductional pathways is activated by H_3 receptors in the brain remains unknown. Although a direct inhibition of adenylyl cyclase could not

be observed in various brain regions [280, 281], H_3 autoreceptors modulate histamine synthesis through the cAMP pathway [282, 283] and H_3 receptor activation inhibits dopamine D_1 receptor-mediated cAMP formation in the rat striatum [284]. Stimulation of H_3 receptors in hippocampal slices activates ERK2, but this effect does not result from a direct coupling to the ERK pathway [220].

Recombinant H_3 receptors display a high level of constitutive (or spontaneous) activity, and in fact most antagonists act as inverse agonists on various responses [263, 277, 285, 286]. Consistent with the physiological relevance of the process, constitutive activity of native H_3 receptors is detected in rodent brain [160, 263]. This constitutive activity of the native H_3 receptor is observed in all brain regions and appears to be one of the highest among G-protein-coupled receptors (GPCRs) [160]. Inverse agonists at H_3 receptors enhance histamine neuron activity by abrogating the brake triggered by constitutive activity of H_3 autoreceptors [263, 287] and are, therefore, important tools to delineate the functions of histaminergic neurons. The recombinant human H_3 receptors expressed at physiological densities also display constitutive activity, suggesting it is present in human brain [160].

9.3.3.2 Responses in Brain Tissues. After its characterization as an autoreceptor present upon histamine neurons, the H_3 receptor was shown to inhibit presynaptically the release of other monoamines in brain and peripheral tissues as well as of neuropeptides from unmyelinated C fibers. In neurons, H_3 receptors inhibit the in vitro release of various neurotransmitters, including histamine itself, noradrenaline, serotonin, dopamine, glutamate, GABA, and tachykinins [24, 131, 132, 288]. This presynaptic inhibition presumably results from a direct G-protein-mediated blockade of voltage-gated calcium channels [289–292]. In brain slices or isolated neurons, somatodendritic H_3 autoreceptors also inhibit the firing rate of histaminergic neurons by inhibiting multiple high-threshold calcium channels [293, 294]. Their tonic activation is shown by the increase in firing induced by thioperamide, a standard antagonist/inverse agonist [295]. A coupling of H_3 receptors to the neuronal Na^+/H^+ exchanger has been found in neuroblastoma cells and cardiac adrenergic neurons [296].

The inhibition mediated by H_3 autoreceptors is now well established as a major control mechanism for the activity and functions of histaminergic neurons. However, the physiological role of the H_3 receptors present on other neuronal populations remains largely unknown.

H_3 heteroreceptors inhibit dopamine synthesis [297] and release [298] but do not regulate dopamine neuron activity in vivo under basal conditions [299–301]. However, the inhibition of dopamine neuron activity by H_3 heteroreceptors may become operating after methamphetamine administration, which is known to increase histamine release [302, 303], as shown by the potentiation of methamphetamine-induced accumbal dopamine release induced by H_3 receptor antagonists/inverse agonists [304]. H_3 heteroreceptors inhibit in vitro noradrenaline release in the brain from various species, including human [244, 305, 306], but play also a minor role on noradrenaline turnover [299–301] and release in vivo [307]. H_3 heteroreceptors also inhibit serotonin release in the cortex [308] and substantia nigra [309] but do not affect serotonergic transmission under basal conditions in vivo [310]. In the striatum, dentate gyrus, and amygdala, H_3 receptor activation inhibits glutamatergic transmission in vitro [311–314], but the standard antagonist/inverse agonist

thioperamide does not increase synaptic potentials in the freely moving rat [315]. H_3 receptors inhibit GABA release in rat striatum, substantia nigra, and hypothalamus [291, 316, 317].

Acetylcholine release is also inhibited by H_3 receptors, but the latter are presumably not located on cholinergic axon terminals [318, 319]. The increase in endogenous acetylcholine release induced in vivo by H_3 receptor antagonists/inverse agonists is due to blockade of autoreceptors, increase in endogenous histamine release, and subsequent activation of H_1 or H_2 receptors [178, 179, 246, 247]. Whereas this indirect activation of the cholinergic tone is observed in several brain regions, the opposite modulation has been reported in the amygdala, the increase in acetylcholine release being induced by H_3 receptor agonists [320, 321].

9.3.3.3 Distribution. A detailed autoradiographic mapping of the rat H_3 receptor was first achieved using the highly selective agonist [3H](*R*)- α -methylhistamine [322] and more recently with the selective antagonist [^{125}I]iodoproxyfan [323] (Fig. 9.2). The comparison with the distribution of H_3 receptor mRNAs provides evidence for the presence of H_3 receptors on many neuronal perikarya, dendrites, and projections. The highest receptor densities are found in the cerebral cortex, basal ganglia, olfactory tubercles, amygdala, and tuberomammillary nucleus. Receptor densities are particularly high in the striatum, where lesions indicated that most H_3 receptors are present on projection neurons [195, 322, 324, 325]. In agreement, high densities of H_3 receptor mRNAs are also found in the striatum from rat [264, 323], guinea pig [271], and human [326]. H_3 receptors present on striatonigral neurons account for the dense binding in the substantia nigra pars reticulata [327]. H_3 receptors are also expressed in striatopallidal projection neurons [328] and account for the dense binding in the external globus pallidus in rat [323] and human [191, 326]. This expression in the external pallidum is increased in Parkinson's disease [326] and dramatically reduced in Huntington's disease [329].

H_3 receptor binding sites were not detected until day P9 [195], but H_3 receptor mRNAs could be observed as early as day E14, presumably due to the higher sensitivity of the probes [64].

H_3 receptor functions have primarily been studied with standard agonists and antagonists/inverse agonists and more recently with mice lacking H_3 receptors [330–333].

9.3.4 Histamine H_4 Receptor

Several groups recently cloned an additional histamine receptor subtype, termed H_4 , via in silico analysis of human genomic databases [334–339]. Its gene structure, coding sequence, and pharmacology are clearly related to the H_3 receptor. Only few selective ligands have so far been designed for this novel receptor and antagonists mainly display anti-inflammatory properties [340–342]. Its expression in the brain is very low, if any, and was detected only in some studies [339, 343]. Its highest level of expression is observed in hematopoietic tissues and cells (bone marrow, spleen, leucocytes).

9.3.5 Interaction with NMDA Receptors

Histamine potentiates NMDA-evoked currents in acutely isolated rat hippocampal neurons and in cultured rat hippocampal or cortical neurons [344–346].

Pharmacological studies showed that this effect could not be ascribed to activation of the metabotropic histamine receptors, since it is neither mimicked nor antagonized by several of the H_1 , H_2 , and H_3 receptor agonists or antagonists. This potentiation of NMDA receptors by histamine is slightly glycine dependent, voltage independent, and occluded by spermine. Moreover, this effect is selective for receptors containing the NR1A/NR2B NMDA receptor subunits and is likely to result from a direct potentiation of the NMDA receptor by histamine through its polyamine modulatory site [344, 345, 347].

Histamine may play a role in modulating the functions of NMDA receptors in vivo. It facilitates the NMDA-induced depolarization of projection neurons in cortical slices [170] and phase shifts the circadian clock by a direct potentiation of NMDA currents in the suprachiasmatic nucleus [348]. Furthermore histamine, presumably acting through NMDA receptors, facilitates the induction of long-term potentiation [349], causes long-lasting increases of excitability in the CA1 region of rat hippocampal slices [173], and ameliorates 7-chlorokynurenic acid-induced spatial memory deficits in rats [350].

The histamine-induced modulation of NMDA responses is higher under slightly acidic conditions [351, 352]. This may lead to enhancement of NMDA receptor-mediated neuronal excitotoxicity [353, 354], such as that observed in a rat model of Wernicke's encephalopathy [355, 356].

9.4 HISTAMINERGIC NEURON ACTIVITY AND ITS CONTROL

9.4.1 Electrophysiological Properties

Cortically projecting histaminergic neurons display typical electrophysiological properties [25, 294]. Their voltage responses, with strong inward and outward rectifications, are similar to those of other aminergic neurons but allow the unambiguous identification of histaminergic neurons in the tuberomammillary nucleus, non-histaminergic neurons in this region exhibiting quite different properties. Histamine neurons are pacemakers that display a regular spontaneous firing. Their rate of firing in vivo is higher during waking, and in vitro, they fire at rates similar to their activity during waking in vivo. Membrane conductances for Na^+ , Ca^{2+} , and K^+ are responsible for their pacemaker properties and maintain a stable and slow firing rate (below 3 Hz) in the absence of extrinsic control [357]. During spontaneous activity, the action potential is generated by a tetrodotoxin-sensitive persistent Na^+ current [358, 359] and a subthreshold voltage-dependent Ca^{2+} current [360]. Voltage- and calcium-dependent potassium currents are involved in membrane repolarization [294]. The action potential is followed by an afterhyperpolarization, which limits the firing rate. The return to the membrane resting potential is delayed by activation of a transient fast outward K^+ current of the A type [361] and facilitated by the hyperpolarization-activated I_h current [362].

9.4.2 Modulation of Histaminergic Neuron Activity In Vitro

Endogenous histamine is released by K^+ -induced depolarization of brain slices via a Ca^{2+} -, temperature- and glucose-dependent process [11–13, 363]. The

autoreceptor-regulated modulation of histamine synthesis in and release from brain neurons is well documented [23]. It was initially evidenced in brain slices or synaptosomes [21, 364, 365] after labeling the endogenous pool of histamine using the [^3H] precursor [13]. Exogenous histamine decreases the release and formation of [^3H]histamine induced by depolarization, and analysis of these responses led to the pharmacological definition of H_3 receptors. The autoregulation was found in various brain regions known to contain histamine nerve endings, suggesting that all terminals are endowed with H_3 autoreceptors.

Regulation of histamine synthesis was also observed in the posterior hypothalamus, and somatodendritic H_3 autoreceptors inhibit the firing of tuberomammillary neurons. This slowing of firing has been observed in slices, cocultures with hippocampus, and isolated histamine neurons and results from the modulation of high-voltage-activated calcium channels [232, 293, 294].

Galanin, a putative cotransmitter of a subpopulation of histaminergic neurons, inhibits histamine release only in regions known to contain efferents of this subpopulation, that is, in hypothalamus and hippocampus but not in cerebral cortex or striatum [366]. In brain slices, galanin also hyperpolarizes and decreases the firing rate of tuberomammillary neurons [367]. It is not known, however, whether these galanin receptors behave as "autoreceptors" modulating galanin release from histaminergic nerve terminals, inasmuch as the tuberomammillary nucleus receives a strong galaninergic innervation from the ventrolateral preoptic area [70, 71]. Other putative cotransmitters of histaminergic neurons failed to affect [^3H]histamine release from slices of rat cerebral cortex [368], and histamine neurons in the tuberomammillary nucleus are insensitive to adenosine [25]. However, GABAergic inhibitory postsynaptic potentials are mediated by GABA_A receptors located on histaminergic neurons [369]. The GABA_A receptors expressed among identified histamine neurons are heterogeneous and contain α_2 and α_5 subunits [370] with different expression levels of γ subunits leading to different sensitivities of histamine neurons to the transmitter [371]. To what extent these receptors play an autoinhibitory role is unclear. Histaminergic neurons contain GABA [46, 47] but the tuberomammillary nucleus also receives a dense GABAergic innervation from the VLPO [70, 71, 80]. In addition, the GABA-mediated inhibition of histamine neurons is controlled by presynaptic GABA_B and adrenergic α_2 receptors [369, 372, 373] and suppressed by dynorphin-containing neurons [295].

Orexins directly excite the histaminergic neurons in vitro [76, 374]. Most histamine neurons express mRNAs and immunoreactivity for both orexin receptors [76, 375–377], but the orexin 2 receptor seems mainly involved. In agreement, the expression of this receptor is stronger than that of the orexin 1 receptor and its absence eliminates the orexin-induced depolarization of histaminergic neurons [378].

Several other systems activate histamine neurons. Serotonin depolarizes histamine neurons and increases their firing rate by activation of $5\text{-HT}_{2\text{C}}$ receptors and a $\text{NCX1 Na}^+/\text{Ca}^{2+}$ exchanger [379, 380]. Glutamatergic α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors coexpressed with $\text{NCKX Na}^+/\text{Ca}^{2+}$ exchangers activate acutely isolated histamine neurons with different desensitization properties [381]. Although a purinergic transmission in the tuberomammillary nucleus has not yet been reported, adenosine triphosphate (ATP) can be coreleased with different transmitters such as GABA and excites individual histaminergic neurons through P2X receptors [382, 383]. Ghrelin, a potent orexigenic

peptide, activates cultured histamine neurons by inhibiting G-protein-coupled inward-rectifier K^+ (GIRK) channels [384], a finding in agreement with the increase in Fos expression observed in the tuberomammillary nucleus after ghrelin administration [385]. Intracellular recordings from rat hypothalamic slices indicate that morphine increases the firing of histaminergic neurons [386], and histamine release in mouse cerebral cortex is enhanced by stimulation of μ -opioid receptors [387]. Histamine release is also enhanced by stimulation of nicotinic receptors in rat hypothalamus slices [388], an effect which may result from activation of α -bungarotoxin-sensitive α_7 nicotinic receptors expressed in histamine neurons [389].

Inhibitory actions on histaminergic neurons have also been found. Besides GABA, isolated neurons with larger somata are inhibited by strychnine-sensitive glycine receptors [390]. Nociceptin inhibits the firing of histaminergic neurons by activating GIRK channels [386]. [3H]Histamine synthesis and release are inhibited in various brain regions by stimulation of not only autoreceptors but also α_2 -adrenergic receptors [391, 392], M_1 -muscarinic receptors [393], and κ -opioid receptors [394]. Since these regulations are also observed with synaptosomes, all these receptors presumably represent true presynaptic heteroreceptors. Hypothalamic histamine release differs also with sex [395], a finding which may result from the presence of estrogen receptors in most histaminergic neurons [396, 397].

9.4.3 Changes in Histaminergic Neuron Activity In Vivo

9.4.3.1 Physiological Changes. In contrast to mast cells and microglial cells, histamine neurons constitute a rapidly turning over pool in the brain [23]. Isotopic methods [398] as well as methods based upon the rates of decrease of histamine levels after inhibition of HDC [92, 399, 400] or increase in *tele*-methylhistamine (*t*-MeHA) levels after MAO inhibition [401–403] lead to a mean half-life of neuronal histamine of ~ 30 min. This value does not markedly vary among brain regions, although it is slightly higher in the hypothalamus. Both neurochemical and electrophysiological studies indicate that the activity of histaminergic neurons is maximal during arousal [23]. In rat hypothalamus, histamine levels are low whereas synthesis is high during the dark period, suggesting that neuronal activity is enhanced during the active phase [404, 405]. In mouse cerebral cortex, striatum, and hypothalamus, *t*-MeHA levels are doubled at the end of the dark phase of the cycle as compared with the beginning of the light phase [406] and are significantly enhanced during the daytime in human cerebrospinal fluid (CSF) [407]. Histamine release from the anterior hypothalamus or frontal cortex of freely moving rats or cats, evaluated by in vivo microdialysis, reaches its maximal level during periods of wakefulness [408–410]. Such state-related changes are also found in single-unit activity recordings performed in the ventrolateral posterior hypothalamus of freely moving rats or cats. Neurons identified as histaminergic neurons exhibit a circadian rhythm of their firing rate, highest during waking and falling silent during deep slow-wave or paradoxical sleep (hence referred to as “waking-on” or “rapid eye movement (REM)–off” neurons) [411–413]. In agreement, Fos expression is enhanced during periods of wakefulness in all histaminergic neurons [414].

An important determinant of this circadian rhythm of tuberomammillary histaminergic neuron activity is the GABAergic inhibitory input from the VLPO which is activated during sleep [70, 71, 80]. Muscimol, a GABA_A receptor agonist, decreases

histamine turnover in the mouse brain [415]. Histamine turnover in the brain is also rapidly reduced after administration of GABAergic sedative drugs such as barbiturates and benzodiazepines [398, 416], presumably as a result of their interaction with GABA_A receptors present on histaminergic neurons [369]. In vivo microdialysis shows that endogenous GABA as well as systemic administration of muscimol, pentobarbital, diazepam, and halothane inhibits histamine release in the rat brain [417–419]. GABA_A receptors present in the tuberomammillary nucleus play a key role in the sedative component of anesthesia. Microinjection of muscimol in the tuberomammillary nucleus produces sedation in rats and cats [420, 421], and systemic administration of muscimol, propofol, or pentobarbital decreases Fos expression in the tuberomammillary nucleus [421]. Activation of α_2 -adrenergic receptors by the general anesthetic dexmedetomidine [422] and activation of adenosine A_{2A} receptors [423] induce sleep by increasing GABA release in the tuberomammillary nucleus to inhibit histaminergic neurons.

Orexins released from neurons emanating from the lateral hypothalamus enhance histamine neuron activity. Orexin levels are not altered by circadian time [203] but their arousal effect depends on activation of histaminergic neurons [202, 424, 425]. In agreement, an altered histaminergic neurotransmission was reported in orexin receptor-2 mutated dogs, an animal model of narcolepsy [426]. Whether histaminergic neurons could represent a target for modafinil, a well-known wake-promoting drug used for the treatment of narcolepsy, is unclear. Its mechanism of action is poorly understood and its increasing effect on histamine release in vivo is indirect and is observed only after administration of high doses [427]. Fos immunoreactivity in the tuberomammillary nucleus is enhanced by administration of high [428] but not low [429] doses. Prostaglandin E₂ also induces wakefulness through activation of the histaminergic system via EP₄ receptors present on histamine neurons [430]. The very high histamine levels observed in the brain of rats with portocaval anastomosis are involved in the sleep disturbances observed in hepatic encephalopathy [431, 432]. The histamine turnover and fiber density are increased during hibernation, which may suggest that histamine neurons maintain the hibernating state or are involved in arousal from hibernation [433].

Feeding increases in vivo endogenous histamine release in the rat hypothalamus [434] and enhances Fos expression in histaminergic neurons [435]. A strong decrease in histamine neuron activity was found in Zucker fatty (*fa/fa*) rats, which have dysfunctional leptin receptors [436], as well as in obese leptin receptor-deficient *db/db* mice or leptin-deficient *ob/ob* mice [437]. That histaminergic neurons are a target for leptin in its control of feeding is also shown by the enhancement of histamine turnover and release induced in rat hypothalamus by leptin administration [437–439]. This effect of leptin may be indirect since it was not observed in two studies following intracerebroventricular administration or after transection of chorda tympani nerves, a branch of the facial nerve which mediates taste information and activates the histaminergic system [439–441]. In agreement, histamine neurons express few leptin receptors [442], and hypothalamic α -MSH (α -melanocyte stimulating hormone)-containing neurons may relay the effects of leptin on histaminergic neurons [79].

The effect of stress on histamine neuron activity depends on the stressful procedure [23]. In addition, Fos immunohistochemistry revealed a strong heterogeneity among histaminergic neurons in their response to various stress challenges [443]. Restraint stress increases histamine turnover [444] and handling stress increases

its release in vivo [445]. In contrast, food-deprived activity stress, an animal model for anorexia nervosa, decreases histamine neuron activity [446]. Changes in the metabolism and release of histamine observed in vivo after occlusion of the middle cerebral artery in rats suggest that the histaminergic activity is enhanced by cerebral ischemia [447, 448].

Ethanol decreases histamine turnover [449], and histamine levels and fiber densities are lower in the brain of genetically ethanol-sensitive rats than in ethanol-insensitive rats [450] and higher in the brain of an alcohol-preferring rat line [451].

An increase of *t*-MeHA levels with age has been reported in human CSF [452]. Changes in histamine neuron activity also occur in various neuropsychiatric diseases. *t*-MeHA levels are increased in the CSF of schizophrenic patients [453]. Histamine levels are unaffected in the brain of MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine)-treated mice [454] but increased in the brain of patients with Parkinson's disease, where they are associated with a strong increase in histaminergic innervation in the substantia nigra [455, 456]. A reduced number of histamine neurons [457] and a significant decrease of HDC activity and histamine levels in the hypothalamus, hippocampus, and cortex [458, 459] have been found in Alzheimer's brains. Similar deficits have been reported in frontal cortex of patients with Down syndrome [459].

9.4.3.2 Pharmacological Changes. Whereas H_1 and H_2 receptors are apparently not involved, inhibition mediated by the H_3 autoreceptor constitutes a major regulatory mechanism for histaminergic neuron activity under physiological conditions [23]. Administration of selective H_3 receptor agonists reduces histamine turnover [22, 280] and release in vivo [460, 461]. In contrast, H_3 receptor antagonists/inverse agonists enhance histamine turnover [22, 263, 280, 462] and release in vivo [109, 463, 464], indicating that autoreceptors are tonically activated. In agreement, administration of H_3 receptor antagonists/inverse agonists also increases HDC mRNA expression [465, 466] and Fos immunoreactivity [412] in the tuberomammillary nucleus.

Agents inhibiting histamine release in vitro via stimulation of presynaptic α_2 -adrenergic receptors reduce histamine release and turnover in vivo [391, 467]. A similar inhibition is induced by activation of muscarinic heteroreceptors [393, 468, 469]. Whether these heteroreceptors are tonically activated under basal conditions remains unclear: Systemic administration of antagonists of these receptors does not enhance histamine turnover but in vivo microdialysis studies show that their local perfusion increases histamine release [467, 468, 470].

Activation of central nicotinic receptors inhibits histamine turnover [469]. Several types of serotonergic receptors are likely to modulate histamine neuron activity in vivo. 5-HT_{1A} receptor agonists inhibit histamine turnover [471], a 5-HT_{2A} receptor antagonist enhances histamine turnover [472], and a mixed 5-HT_{2C/2A} receptor antagonist decreases histamine release in vivo [473]. Perfusion of the posterior hypothalamus with dopamine D₂ receptor agonists enhances histamine release in vivo [474] and stimulation of D₂ (but not D₃) receptors by endogenous dopamine released by methamphetamine increases histamine neuron activity [302, 303].

Morphine and μ -opioid receptor agonists enhance histamine release and turnover in brain [387, 475–477]. Δ^9 -Tetrahydrocannabinol decreases histamine turnover [478], but local or systemic administration of selective cannabinoid CB₁ receptor agonists increases in vivo histamine release [479]. NMDA receptors increase in vivo release of histamine from the anterior hypothalamus [480]. Activation of NMDA and

non-NMDA receptors in the diagonal band of Broca, the lateral preoptic area, and the anterior hypothalamic area led to inhibition or enhancement of firing rates of tuberomammillary neurons [80].

9.5 PHYSIOLOGICAL ROLES OF HISTAMINERGIC NEURONS

Owing to the use of an increased number of experimental tools, for example, histamine H_3 receptor antagonists to activate histaminergic neurons [22], α -fluoromethylhistidine to block brain histamine synthesis [92], mutant mice lacking L-histidine decarboxylase [93] or the histamine H_1 receptor [182], the functional role of histaminergic neurons has been considerably clarified during recent years.

9.5.1 Arousal

Our initial proposal, in 1977 [18], that histaminergic neurons play a critical role in arousal was based upon a few experimental arguments that were put together:

1. The disposition of histaminergic neurons, at this time recently uncovered by lesion studies [7], with their highly divergent ascending projections to many telencephalic brain areas, was reminiscent of those of other aminergic systems, that is, catecholaminergic and indolaminergic systems, with an already well demonstrated role in control of sleep and arousal.
2. Intracerebroventricular administration of histamine in rabbits had been shown to induce electroencephalographic desynchronizations that were blocked by mepyramine [481, 482].
3. The well-known sedative properties of “antihistamines” could be related to blockade of histamine actions at H_1 receptors that had recently been evidenced to be present in brain [16].

This early proposal has been, since then, confirmed initially by experiments performed by Lin and Jouvet in cats [483] and Monti in rats [23], and a large variety of studies are now available to strengthen the view that the histaminergic system is one of the major neuronal systems controlling cortical activation and wakefulness (reviewed in [484]).

In agreement, ablation of these neurons, inhibition of histamine synthesis, and release or action via the H_1 receptor all decrease wakefulness and increase deep slow-wave sleep; conversely inhibition of histamine methylation or facilitation of histamine release via H_3 autoreceptor blockade increases arousal [462]. Knockout mice lacking the L-histidine decarboxylase gene ($HDC^{-/-}$ mice) show an increase in paradoxical sleep and a decrease in theta-rhythm power during waking, without, however, a deficit in daily amount of waking; nevertheless these animals introduced in a novel environment remained awake only during a few minutes whereas wild-type animals remain awake for several hours under such circumstances [93].

The arousing effect of histamine might result from H_1 and H_2 receptor-mediated depolarization of thalamic relay neurons which induces a shift of their activity from burst firing (predominating in deep sleep, during which they are poorly responsive to

sensory inputs) to single-spike activity (predominating in arousal, during which sensory information is more faithfully relayed) [485]. Arousal may also result from H_1 receptor-mediated excitation of neocortical pyramidal neurons via the same mechanism as in thalamus, that is, reduction of a background leakage potassium current [163]. Finally arousal may occur indirectly via H_1 receptor-mediated excitation of ascending cholinergic neurons within the nucleus basalis or mesopontine tegmentum [171, 483], which also induces cortical activation.

All these cellular actions of histamine, together with observations that tuberomammillary neuron firing and brain histamine turnover are maximal during wakefulness, suggest that histaminergic systems make an important contribution to the control of arousal. Histamine release measured by microdialysis in the feline anterior hypothalamus is the highest during wakefulness, intermediate during slow-wave sleep, and the lowest during paradoxical sleep, with about a maximal fivefold circadian variation [409].

The circadian changes in histaminergic neuron activity seem to be directed by two major neuronal inputs arising from the anterior/lateral hypothalamus. The first one is a slow-wave sleep-activated inhibitory GABA- and galanin-containing group of neurons arising from the VLPO area [70, 71]; in contrast, the second group of neurons releasing the neuropeptides orexins, which emanate from the lateral hypothalamus, appear to exert opposite actions since disruption of the orexin gene is associated with narcolepsy in dogs and knockout mice [73, 486]. Orexin excites the histaminergic neurons of the tuberomammillary nucleus [76]. The arousing effect of orexins may largely depend upon their activation of histaminergic neurons since the effect is absent in knockout mice deficient in the H_1 receptor [202].

The preoptic/anterior hypothalamus has been known for a long time to also play an important role in the control of sleep/wakefulness alternance because its destruction is followed by a state of prolonged insomnia; however, this state is reversed by inactivation of ventrolateral posterior hypothalamic (presumably histaminergic) neurons [487], indicating that the VLPO neurons exert a tonic inhibition upon a wakefulness center represented by the histaminergic perikarya. In turn histaminergic neurons project heavily to the anterior hypothalamus and locally applied histamine (via H_2 receptor activation) elicits wakefulness, thus witnessing the existence of a reciprocal loop between the two areas that could be involved in the alternance of sleep and wakefulness [488] according to Nauta's long-standing hypothesis (see [484] for a detailed discussion). In contrast, however, sleep-promoting GABAergic neurons in the VLPO do not appear to be affected by histamine *in vitro* [489].

Other monoaminergic, that is, catecholaminergic and indolaminergic, neurons participating in the control of sleep/wakefulness states as well as GABA/galanin VLPO neurons also receive inputs from orexin neurons which are, themselves, likely influenced by photic signals from the suprachiasmatic nucleus. In turn, neurons from the suprachiasmatic nucleus seem to be influenced in a complex manner by histaminergic inputs [490]. Hence a complex neuronal network in the hypothalamus with a series of reciprocal influences involving histaminergic neurons seems to control wakefulness.

The major part played by the H_1 receptor in these processes, confirmed in mutant mice lacking this receptor [204], accounts for the sedating effects of the first generation of "antihistamines," that is, antagonists which easily enter the brain

and are still ingredients of over-the-counter sleeping pills [491, 492]. It may also account for the sedative side effects of many antipsychotic or antidepressant drugs, a large number of which are potent H_1 receptor antagonists and were shown to block [3H]mepyramine binding to the brain receptor in rodents at subtherapeutic dosages [493, 494].

9.5.2 Cognitive Functions

The idea that activation of histaminergic neurons might improve cognitive performances is consistent with their projections to brain areas such as the prefrontal and cingulate cortices or hippocampus, their projections to cholinergic perikarya, their excitatory influences therein, and their positive role in wakefulness. The procognitive role of histaminergic neuron activation was largely established in behavioral studies in rodents using thioperamide or other, more recent, H_3 receptor inverse agonists (reviewed in [495]).

Ciproxifan, a potent and selective H_3 receptor inverse agonist, which strongly enhances histamine turnover in brain, improved attentional performances in the rat five-choice test under conditions similar to those of drugs enhancing cholinergic transmissions [462]. The same drug, as well as thioperamide and several other compounds of the same pharmacological class, also exerted proattentional activity in a five-trial acquisition test performed in spontaneously hypertensive rat pups, often considered as a model for attention deficits and impulsivity in attention-deficit hyperactive disorder (ADHD) patients [496].

Various H_3 antagonists facilitate various forms of learning: memory consolidation, spatial orientation, short-term memory, and working memory [495]. For instance, they improve short-term social memory in rats [497], reverse the scopolamine- or senescence-induced learning deficit in a passive avoidance test in mice [498], and facilitate retention in a footshock avoidance test in mice [499].

Generally H_3 agonists exert opposite effects and the effects of H_3 antagonists are reversed by H_1 antagonists, which suggests that the latter are attributable to enhanced histamine release. In agreement, H_3 receptor knockout mice display enhanced spatial learning and memory [333].

In contrast to the large body of experiments indicating a “procognitive” role of tuberomammillary neurons, Huston and co-workers have repeatedly shown that excitotoxic lesions, aimed at these neuron ablations, improves learning in a variety of tests (e.g., [500]). The discrepancy with data derived from pharmacological approaches might be due to the difficulty to achieve selective histamine neuron ablation [501]. Also a more confusing picture emerges from studies in which the drugs were applied intracerebrally, a procedure which is likely to lead to artifacts [502]. Nevertheless, HDC knockout mice show deficient nonreinforced episodic object memory but improved negatively reinforced water-maze performance [95].

9.5.3 Control of Pituitary Hormone Secretion

Histamine affects secretion of several pituitary hormones [23, 503]. Magnocellular neurons of the supraoptic and paraventricular nuclei are typically excited, an essentially H_1 receptor-mediated response resulting in enhanced blood levels of vasopressin and oxytocin. Histaminergic neurons are activated during dehydration,

parturition, and lactation, and histamine release onto magnocellular neurons participates in the control of these physiological processes by the neurohypophysial hormones [504–506].

Histaminergic neurons may also participate in the hormonal responses to stress. In agreement they are activated during various forms of stress and heavily project to hypothalamic or limbic brain areas (e.g., amygdala or bed nucleus of the stria terminalis) involved in these responses. Various pharmacological studies have shown the participation of endogenous histamine via H_1 and H_2 receptor stimulation in the adrenocorticotrophic hormone (ACTH), corticosterone, prolactin, or renin responses to stressful stimuli like restraint, endotoxin, or dehydration [507, 508]. Furthermore, it seems that the activation of various subpopulations of histaminergic neurons within the tuberomammillary nucleus varies according to the nature of stressful stimuli [443, 509].

A high proportion of histaminergic neurons contain estrogen receptors, project to luteinizing hormone releasing hormone (LHRH) neurons in preoptic and infundibular regions, and might constitute, via H_1 receptor stimulation, an important relay in the estradiol-induced preovulatory LH surge [396]. Both estrogen receptors α and β were characterized in large (presumably histaminergic) neurons of the human brain and their role in the control of these neurons activity suggested [397].

9.5.4 Satiation

A satiating role of endogenous histamine is strongly suggested by several observations, but this view is not in agreement with all experimental data.

For instance, weight gain is often experienced by patients receiving first-generation H_1 antihistamines crossing the blood–brain barrier as well as antipsychotics or antidepressants displaying potent H_1 receptor antagonist properties. This eventually results in an increased risk of developing a “metabolic syndrome” in patients chronically treated with such psychotropic agents (e.g., second-generation antipsychotics) [494, 510]. Central infusion of histamine reduces fat accumulation in leptin-resistant obese mice [511]. These effects could reflect the inhibitory role of endogenous histamine on food intake mediated by the H_1 receptor, namely on the ventromedial nucleus [512].

Histamine neurons projecting to the hypothalamus may be responsible for the food intake suppression induced by the fat cell–produced hormone, leptin. In agreement, intracerebroventricular administration of leptin increases hypothalamic histamine release [438], whereas histamine depletion by α -fluoromethylhistidine treatment attenuates leptin-induced feeding inhibition [437]. Aged mice with gene disruption of either the H_1 receptor [209] or the histidine decarboxylase gene [94] display adiposity; also both mice display hyperleptinemia, which suggests the existence of a regulatory loop between hypothalamic histamine neurons and leptin-producing cells, the nature of which remains elusive.

Following the initial observation that the prototypical H_3 receptor antagonist/inverse agonist thioperamide decreases food intake in rats [512], studies using various compounds belonging to this drug class have confirmed that increased brain histamine release in rodents is associated with anorectic and antiobesity effects (reviewed in [513]). For instance, treatment of mice stabilized on a high-fat diet with A-331440, a potent non-imidazole H_3 receptor antagonist, decreased weight

comparably to dexfenfluramine, reduced body fat, and normalized insulin resistance test [514].

Nevertheless not all H_3 receptor inverse agonists elicit such effects (S. Krief, personal communication); thioperamide-induced appetite suppression was attributed to taste aversion to this compound [515], and in a mouse model of H_3 receptor disruption, paradoxical increases in body weight, food intake, and adiposity together with reductions in energy expenditure have been reported [331].

9.5.5 Seizures

The anticonvulsant properties of endogenous histamine were initially suggested from the occurrence of seizures in epileptic patients, particularly children, following administration of high doses of H_1 receptor antagonists crossing the blood–brain barrier, even those devoid of anticholinergic activity [491].

The role of histaminergic neurons in preventing seizures, or even the development of epileptogenesis, presumably, in most cases, via H_1 receptor activation, has been shown in several rodent models of epilepsy [516, 517]. In agreement, drug-induced changes in histamine synthesis, release, or metabolism confirmed the role of the endogenous amine acting via the H_1 receptor in preventing seizure activity elicited in rodents by pentetrazole, transcranial electrical stimulation, or amygdaloid kindling. Consistently, H_3 antagonists inhibit amygdaloid kindled seizures, an effect prevented by H_1 antagonists, which suggests the involvement of endogenous histamine [518]. Even more, studies in histidine decarboxylase- and H_1 receptor-deficient mice indicated that endogenous histamine plays a crucial role not only in amygdaloid kindled seizures but also in the development of amygdaloid kindling [207]. Acquired amygdaloid kindling susceptibility appears associated with reduced histamine synthesis in limbic brain areas [519].

In addition, a protective role of endogenous histamine was convincingly shown in the development of pentetrazole-induced kindling in rats or mice [96, 520] as well as in the development of seizures in EL mice, a model for hereditary temporal lobe epilepsy [521].

In another epilepsy model, kainic acid-induced limbic seizures in the rat, upregulation of the H_1 receptor mRNA is detected in striatum and dentate gyrus, consistent with a regulatory role of this receptor in seizure activity [194].

Taken together all these studies suggest that enhancing brain histamine release via H_3 receptor blockade should represent a novel therapeutic approach for several epilepsies.

9.5.6 Nociception

The antinociceptive effects of histidine loads, H_3 receptor antagonists, and histamine *N*-methyltransferase inhibitors as well as opposite effects of histamine synthesis inhibitors or H_3 agonists support the idea that brain histamine inhibits nociceptive responses such as the mouse hot-plate jump [522]. In contrast, peripherally acting H_3 receptor agonists prevent nociceptive responses such as mouse abdominal constriction by inhibiting sensory C-fiber activity [523]. Activation of spinal H_3 receptors was shown to inhibit mechanical but not thermal nociceptive responses [524].

9.6 ROLE OF HISTAMINERGIC NEURONS IN NEUROPSYCHIATRIC DISEASES

Various approaches tend to establish the implication of histaminergic neurons in neuropsychiatric diseases, although the evidence remains largely indirect due to the poor predictability value of most animal models and the paucity of drugs affecting histaminergic transmission that were tried in these human diseases so far.

9.6.1 Histamine, Schizophrenia, and Antipsychotic Drug Actions

Overdose of a variety of classical H₁ antagonists was repeatedly reported to result in toxic psychoses with hallucinations resembling schizophrenia, and the hallucinogenic potential of these drugs has even led to abuse [491].

On the other hand, methamphetamine, a drug with hallucinogenic potential and to which schizophrenic patients seem hyperresponsive, releases histamine in rodent brain areas, an indirect effect mediated by stimulation of D₂ and not D₃ dopamine receptors [302, 303, 472]. Even more, endogenous dopamine appears to exert a tonic stimulation of histamine neurons since typical neuroleptics (e.g., haloperidol) decrease their activity. In contrast, atypical neuroleptics (e.g., clozapine) enhance histamine turnover, an effect related to 5-HT₂ receptor blockade and possibly underlying their procognitive properties [472]. The locomotor activation elicited in rodents by amphetamine and other dopaminergic agonists is attenuated by H₃ receptor blockade [525]. Repeated amphetamine administration to rodents which results in behavioral sensitization to dopamine agonists, a cardinal feature of schizophrenia, is accompanied by enhanced histamine release, which presumably reflects an enhanced tonic dopaminergic influence on histaminergic neurons [302, 303]. In another animal model of psychosis, the locomotor stimulation induced in rodents by the NMDA antagonist dizocilpine, a “psychotogenic” agent, is also partially blocked by H₃ receptor inverse agonists (R. Faucard, unpublished observation). In two other models of schizophrenia in which sensorimotor gating deficits, which are considered as cardinal signs of the disease, were monitored in rodents, for example, prepulse inhibition of a startle response or the auditory-evoked N40 electroencephalographic wave, a normalization was reported upon administration of these drugs [526]. In one comprehensive study, an enhanced level of *t*-MeHA, the major histamine metabolite, was detected in the CSF of schizophrenic patients, either treated or nontreated by neuroleptics [453]. Ciproxifan, an H₃ receptor antagonist/inverse agonist, potentiates neurochemical and behavioral effects of haloperidol in the rat [328].

In several open studies famotidine, an H₂ antagonist, was found to improve schizophrenic patients, a finding which remains to be confirmed in control studies. A previous claim of association between polymorphisms of the H₂ receptor gene and schizophrenia could not be confirmed [216].

These various observations, although not easily forming a coherent picture, suggest that histaminergic neuron activity is enhanced in schizophrenic patients and that blockade of H₂ and/or H₃ receptors might be useful in schizophrenia treatment.

9.6.2 Histamine and Alzheimer's Disease (AD)

In spite of some initial inconsistencies, several neuropathological studies have clearly documented a deficit in histaminergic neurotransmission in Alzheimer's disease (AD).

Numerous neurofibrillary tangles are found in the tuberomammillary nucleus of the AD brain, but most of them are extracellularly located and few are encountered within the histamine-immunoreactive neurons: They were suggested to correspond to remnants of degenerated histaminergic neurons [42, 457]. In agreement, in some (e.g., frontal or temporal cortex, hippocampus) but not all cortical areas of AD brains, there is a decrease of histamine and histidine decarboxylase levels that may reach up to ~50% [458, 459], although these indices of histaminergic fiber degeneration may not reach corresponding indices for cholinergic neurons. Furthermore, there is some evidence that the activity of remaining histaminergic neurons is reduced: Cell and Golgi apparatus size [397] and the expression of the *hdc* gene (S. Trottier and D. F. Swaab, personal communication) are reduced in neurons of the tuberomammillary nucleus.

In addition histamine H₁ receptor abundance, assessed by PET, is significantly reduced in AD patients, particularly in frontal and temporal brain areas [199].

Decreased histaminergic input may affect cholinergic neuron activity in nucleus basalis [171] and acetylcholine release in cortical areas. Taking into account an additional direct positive influence of histamine on attention and memory, this indicates that the histaminergic deficit may participate in the cognitive impairments of AD; correlatively, enhancing histaminergic neurotransmission (e.g., by H₃ receptor antagonists, which were found to compensate cognitive deficits elicited by blockade of cholinergic transmission in rodents) may constitute a novel, symptomatic treatment of the disease. Interestingly, the drug tacrine was even more potent in inhibiting histamine *N*-methyltransferase, the main histamine-metabolizing enzyme, than acetylcholinesterase [113].

In Down syndrome, in which neuropathological changes are similar to those seen in AD, a deficit in histaminergic neurons was also documented [459].

9.6.3 Histamine and Parkinson's Disease

Histamine neurons, which project abundantly in the striatal complex, do not appear to degenerate during Parkinson's disease as judged from levels of L-histidine decarboxylase activity [527] and histamine [455] in postmortem samples of striatum. In contrast, the density of histaminergic fibers in substantia nigra pars compacta and reticulata seems increased in the disease, a change possibly reflecting a compensatory process to dopaminergic neuron depopulation [456].

The interactions between nigrostriatal dopaminergic and histaminergic neurons seem rather complex. Dopaminergic neurons express presynaptic H₃ receptor exerting an inhibitory action on the amine release [298]. Ciproxifan, a potent inverse agonist at the H₃ receptor, strongly potentiated the effect of methamphetamine on proenkephalin expression in rat striatum but depressed its effect on prodynorphin and substance P expression, thus indicating a differential modulation of the activity of striatonigral and striatopallidal neurons [528]. This suggests that the modulatory role of H₃ receptors upon the nigrostriatal complex might find applications in the treatment of Parkinson's disease. In agreement, thioperamide [529] was found to potentiate the levopoda-induced turning behavior of hemiparkinsonian rats.

9.6.4 Histamine and Other Neuropsychiatric Disorders

Anxiety might be increased by endogenous histamine acting at the H₁ receptor. In agreement, H₁ receptor knockout mice display significantly less anxiety in the elevated maze test [182]. However, the utility of H₁ receptor antagonists in anxiety disorders is not established. In addition, H₃ receptor knockout mice showed reduced measures of anxiety [333].

ADHD may benefit from enhanced histamine release as suggested by the therapeutic effect of amphetamine in children and the attention-enhancing effects of an H₃ receptor antagonist in the rat [462]. The diminished cognitive performances of spontaneously hypertensive rat pups, a model for ADHD, are improved by H₃ receptor antagonists, presumably as a result of their histamine-releasing effects [496].

Antidepressant-like effects in the mouse forced swim test result from enhanced histamine release and H₁ receptor activation [530].

9.7 CONCLUSION

This chapter testifies how our knowledge of the molecular neurobiology of cerebral histaminergic systems and their implications in physiological functions (e.g., arousal, cognition, or control of food intake) has progressed during the last years. This appears as the result of the development of reliable research tools such as selective ligands for the various receptor subtypes or genetically modified mice. In contrast, little is known, so far, about the possible implications of histaminergic neurons in neuropsychiatric diseases and the therapeutic utility of psychotropic drugs affecting their activity. H₃ receptor antagonists (or inverse agonists) which markedly enhance brain histamine release are currently undergoing clinical trials in several CNS disorders. It seems likely that such studies will teach us a lot about the role of histamine in the human brain.

10.1 BACKGROUND/RECEPTOR CLASSIFICATION

L-Glutamate is the major excitatory neurotransmitter in the mammalian central nervous system. There have been significant advances in our understanding of the

molecular physiology of the proteins activated by glutamate (metabotropic and ionotropic glutamate receptors) as well as the pharmacology of agents that interact with these proteins. The original classification of ionotropic glutamate receptors was based on pharmacological selectivity and included receptor subtypes preferentially responsive to *N*-methyl-D-aspartate (NMDA), kainic acid (KA), and quisqualic acid [1–3]. Subsequent studies showed that quisqualate also activated inositol phospholipid hydrolysis in hippocampal slices, cultures of cerebellar granule cells and striatal cells, providing some of the first evidence for the existence of metabotropic glutamate receptors [4, 5]. In addition, the discovery that α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) was a more selective agonist for quisqualate receptors than quisqualate itself [6] prompted a change in nomenclature of non-NMDA receptors to AMPA and kainate receptors [7]. Ensuing molecular biological studies have confirmed the fitness of this classification scheme through identification of separate genes encoding distinct subunits for NMDA, AMPA, and kainate receptors (for review, see [8]).

10.1.1 Glutamate Synthesis and Storage

It is now understood that interactions between neurons and glia play an important role in the storage and synthesis of glutamate (reviewed by [9]). Following release, glutamate is removed from the synaptic cleft and extracellular space by cellular uptake. Both neurons (presynaptic and postsynaptic) and glial cells express functional glutamate transporter proteins that use electrochemical gradients to drive glutamate uptake (reviewed in [10]). In nerve terminals, glutamate is transported into synaptic vesicles via a vesicular glutamate transporter (VGLUT1 and VGLUT2) [11]. As such, glutamate may become a metabolic substrate or be used as a transmitter by exocytosis. In astrocytes, it appears that following uptake, glutamate can be converted to glutamine by glutamine synthetase and/or converted to α -ketoglutarate (by glutamate dehydrogenase or aspartate aminotransferase) [12]. Glutamine and α -ketoglutarate can be released from astrocytes and be taken up by neurons. Neuronal glutamine can be converted to glutamate by the adenosine triphosphate (ATP)-dependent enzyme glutaminase and α -ketoglutarate to glutamate by transamination.

10.1.2 Ionotropic Glutamate Receptor Subtypes

Within each of the three ionotropic glutamate receptor groups there are individual subunits; seven for NMDA, four for AMPA receptors, and five for KA receptors (Fig. 10.1). For each receptor type, it is likely that four subunits assemble to form an ion channel, that, dependent upon subunit composition, is permeable to Na^+ and Ca^{2+} ions. In addition to this tetrameric structure, NMDA, AMPA, and KA receptors share similar subunit transmembrane topology with an extracellular amino terminus (S1 region), a first transmembrane region, a pore forming region that consists of a loop that enters the plasma membrane and returns to the cytoplasm, a transmembrane region that forms a large extracellular loop (S2), and a third transmembrane region that enters the cell and forms a carboxy terminus (Fig. 10.2). Based upon crystal structure information, ligand binding for glutamate (and other orthosteric agonists) appears to be between the S1 and S2 regions [13, 14].

Figure 10.1 Receptor classification.

Figure 10.2 Structure of generic ionotropic glutamate receptor.

10.1.3 NMDA Receptors

N-Methyl-D-aspartic acid (Fig. 10.3) was one of the early compounds synthesized to study the structure–activity relationships of the natural excitatory acidic amino acids, L-glutamate and L-aspartate, and proved to be considerably more potent than the endogenous substances [15, 16]. Interestingly, unlike these two natural amino acids which showed only limited stereoselectivity, NMDA was far more potent as an excitant than *N*-Methyl-L-aspartic acid [17]. Over the next 10–15 years, NMDA gave

Figure 10.3 NMDA receptor orthosteric agonists.

its name to a subtype of receptor that was sensitive to a series of structurally distinct antagonists, discovered with some degree of serendipity and a lot of hard grind by chemists and biologists alike. These early compounds included magnesium ions [18], α,ϵ -diaminopimelate (DAP) [19], α -aminoadipate (Fig. 10.3) [20, 21], and 3-amino-1-hydroxypyrrolidin-2-one (HA-966; see Fig. 10.9 below) [19, 22], each of which antagonized NMDA-induced excitations but were far less effective against quisqualate- or kainate-induced excitations of spinal neurones. Pharmacological division between quisqualate (now AMPA) and kainate receptor subtypes resulted from the use of glutamic acid diethylester [2, 6] and later compounds as described in other sections of this chapter. The structural diversity of the early NMDA antagonists was a forerunner for the elucidation of multiple sites on the NMDA receptor complex that will form the main part of this section.

Alongside these pharmacological studies were parallel attempts to show the importance of NMDA and the other glutamate receptor subtypes in synaptic transmission [1, 19, 20, 23]. Better antagonists were needed. For the NMDA receptor, this soon occurred with the marked improvement in selectivity and potency of (*R*)-2-amino-5-phosphonopentanoate (Fig. 10.3) [24], the ω -phosphonate analog of D- α -aminoadipate. Studies with D-AP5, as it is commonly called, led to demonstrations of the importance of the NMDA receptor in synaptic plasticity [25], in neuronal cell death [26], and in convulsive states [27] and a general interest in their role in neurological conditions (see [28]). Indeed, NMDA antagonists have been shown to have potential clinical value in such apparently diverse neurological conditions as stroke [29], epilepsy [30], and pain [31]. In such conditions overactivity of the glutamatergic system leads to membrane depolarization, relief of the voltage-dependent magnesium block of the NMDA receptor channel (see below), calcium entry, and subsequent cascade of intracellular events leading to specific symptomatology.

A subsequent finding that the psychoactive drugs ketamine and phencyclidine (see Fig. 10.10 below) were also NMDA antagonists [32] initiated increased interest in the role of these receptors in psychiatric diseases [33]. In particular, the psychoactive properties of phencyclidine and other allosteric antagonists of NMDA [34] underpinned the hypoglutamatergic hypothesis of schizophrenia (see [35]). The discovery that glycine was a necessary coagonist at the NMDA receptor [36, 37] and that polyamines influence NMDA receptor function [38] added to the increasing diversity and to the potential number of molecular sites to design pharmacological agents.

Before considering this pharmacology and its subsequent development in detail, we need to know something of the basic molecular biology and structure of the NMDA receptor. It is now generally accepted that the NMDA receptor is a tetramer of subunits forming a receptor channel complex. Cloning and expression of NMDA receptor units have elucidated seven genes coding for seven subunits, namely GLU_{N1} , GLU_{N2A} , GLU_{N2B} , GLU_{N2C} , GLU_{N2D} , GLU_{N3A} , and GLU_{N3B} (alternatively referred to as NR1, NR2A, etc.) [8, 39]. There are multiple splice variants of GLU_{N1} and distinct anatomical developmental expression of the GLU_{N2} and GLU_{N3} subunits. Each receptor consists of a large extracellular N-terminus, three transmembrane segments, a pore-lining intramembrane loop between the first and second transmembrane segments, a large extracellular loop between the second and third transmembrane segments, and a relatively small intracellular C-terminus. The two large extracellular domains interact via the S1 and S2 segments to form the agonist binding site. Numerous studies have attempted to define the subunit structure of native and recombinant receptors. It is the general consensus that two GLU_{N1} subunits associate with either two GLU_{N2} or two GLU_{N3} subunits or with one of each to form the native receptor; the two GLU_{N2} may be different gene products, but the combinations that exist in native NMDA receptor complexes have not yet been fully defined. In the most common form of the NMDA receptor, glutamate binds to the GLU_{N2} subunits and the coagonist, glycine, binds to the GLU_{N1} subunits. Recently X-ray crystallographic studies on GLU_{N2A} have confirmed that the GLU_{N1} – GLU_{N2A} heterodimer is the functional unit in the tetrameric NMDA receptor [40]. One of the goals of researchers in the NMDA field is to have compounds showing selectivity for the GLU_{N2} subtypes, which will aid in elucidating the function of the various potential associations. It seems likely that the combination of GLU_{N1} and GLU_{N3} subunits is not sensitive to glutamate or NMDA but rather results in an excitatory glycine receptor [41] and, in other heteromeric combinations, expression of GLU_{N3} reduces NMDA-induced currents relative to GLU_{N1} / GLU_{N2} combinations.

In addition, nonhomologous asparagine residues on the GLU_{N1} and GLU_{N2} subunits produces a narrow constriction in the heteromeric ion channel that allows Ca^{2+} but not Mg^{2+} to permeate [42]. This restricted Mg^{2+} access is important for generating the voltage-dependent block that is relieved upon depolarization.

NMDA receptors have a widespread distribution in the central nervous system (for reviews see [43, 44]). However, *in situ* hybridization studies show that some of the GLU_{N2} subunits have a more restricted localization [45, 46]. For example the GLU_{N2C} subunit is expressed almost exclusively in the cerebellum and GLU_{N2D} is found throughout the diencephalon, midbrain, and glomerular layer of the olfactory bulb [45]. Both GLU_{N2A} and GLU_{N2B} have a distinct but widespread distribution in the central nervous system. For instance, GLU_{N2A} but not GLU_{N2B} has a high expression in the cerebellum whereas GLU_{N2B} but not GLU_{N2A} is highly expressed in the septum [45]. Four pharmacologically distinct NMDA receptor subtypes have been identified in the central nervous system and these have been shown to differ in their GLU_{N2} subunit composition [45, 47–49].

There is a change in GLU_{N2} subunit expression during development with GLU_{N2A} being abundant in adults whereas GLU_{N2B} is abundant in the forebrain throughout development to the adult stage. Interestingly, after postnatal days 10–11 there is a switch in cerebellar granule cell expression of GLU_{N2B} messenger ribonucleic acid (mRNA) for GLU_{N2C} and GLU_{N2A} [46, 50]. The GLU_{N2D} subunit

is abundant in the spinal cord and brain stem throughout development but not in the adult (see review by Watanabe [51]).

In adults, *in situ* hybridization studies demonstrated that the GLU_{N3B} subunit is expressed mainly in the ventral horn of the spinal cord (particularly in motor neurons) and in the facial and trigeminal nuclei of the brain stem [41] whereas the GLU_{N3A} subunit is more widely distributed [52, 53].

10.1.4 AMPA Receptors

The AMPA receptor family includes four different genes termed $\text{GLU}_{\text{A1-4}}$ (GluR1–4 or GluRA–D) that encode proteins of approximately 900 amino acids and share approximately 70% amino acid identity [43, 54]. Structurally, these proteins contain a large extracellular N-terminus domain and four hydrophobic domains labeled TM1–TM4 (Fig. 10.2). In reality, evidence suggests that AMPA receptor subunits have only three transmembrane domains (TM1, TM3, and TM4 in the original nomenclature) and a reentrant loop (TM2) on the cytoplasmic side. This reentrant loop is believed to line the pore of the ion channel, and so is sometimes referred to as the P domain. This topology indicates that both the large N-terminus and the region between TM3 and TM4 are extracellular. The region of the N-terminus, immediately adjacent to TM1 (designated S1), and the region between M3 and M4 (designated S2) have been crystallized and shown to form the ligand binding core (LBC) having an upper and lower domain that gives rise to a “clamshell” configuration with the orthosteric recognition site being localized within the mouth of the clamshell (Fig. 10.2) [13, 55].

Functional AMPA receptors are proposed to be tetramers that can be generated by the assembly of one or more of the protein subunits $\text{GLU}_{\text{A1-4}}$, yielding homomeric or heteromeric receptors [56]. $\text{GLU}_{\text{A1-4}}$ subunits can be modified posttranscriptionally to further increase the diversity of AMPA receptors. RNA editing occurs at two different positions within the AMPA receptor genes. A glutamine residue (Q; CGA) in the pore region of GLU_{A2} is edited to give an arginine (R; CGG). In fully developed adult animals, virtually all of the GLU_{A2} subunit is edited at this site. This edited residue significantly reduces calcium permeability, decreases single-channel conductance, and reduces rectification of the AMPA receptor [57, 58]. A second site in the extracellular domain between TM2 and TM3 is edited from an arginine (R; AGA) to a glycine (G; GGA) in GLU_{A2} , GLU_{A3} , and GLU_{A4} . This edited residue can alter the time course of recovery from desensitization [59].

Additional complexity among AMPA receptors results from alternative splicing in the extracellular S2 region in $\text{GLU}_{\text{A1-4}}$. This region can contain one of two different exons, referred to as flip (i) and flop (o) [60]. The flip and flop exons encode a 38-amino-acid sequence that differs between the two isoforms by only 7 amino acids. These different isoforms show distinct cell-specific and developmental expression patterns in the brain [46, 60]. Further, several functional consequences of this alternative splicing have been identified. In general, receptors composed of flip subunits desensitize more slowly than receptors composed of flop subunits [61, 62]. AMPA receptors composed of flip or flop subunits also show differential sensitivity to positive allosteric modulation [63]. As described in further detail below, the sensitivity of AMPA receptors to positive allosteric modulation provides a mechanism by which glutamatergic synaptic transmission can be enhanced in the central nervous system and may represent a novel approach for the treatment of disease.

On the basis of recent structure–function studies, a model of the mechanisms by which AMPA receptors gate synaptic current has emerged. Evidence indicates that the tetrameric receptor is formed by dimerization of two LBCs of adjacent subunits that in turn dimerize with the dimer of the other two LBCs [64]. Activation of AMPA receptors is initiated by binding of glutamate to each of the four LBCs, leading to the closure of the upper and lower domains of each LBC which is predicted to direct a conformational change in the ion channel gate, permitting ion flux through the channel pore [64]. Termination of current flow can occur via two mechanisms. Deactivation reflects closing of the channel upon removal of glutamate and subsequent release of agonist from the LBC. Desensitization occurs in the continued presence of glutamate and reflects a destabilization and subsequent rearrangement of the intradimer interface that is predicted to uncouple the closing of the LBCs from the channel gate, permitting closure of the ion channel. Interestingly, crystallographic data have revealed that the flip/flop cassette in the S2 region is located at the intradimer interface and is associated with the “hinge” of the clamshell region of the LBC [64]. Differences in the desensitization rates of flip and flop receptors have been shown to depend on the identity of only three amino acid residues in the flip–flop region (Thr765, Pro766, and Ser775 in flip and Asn765, Ala766, and Asn775 in flop) and these three residues are postulated to confer their kinetic differences by directly and/or indirectly influencing the stability of the dimer interface between adjacent subunits [62].

The majority of neurons in the central nervous system display rapid excitatory synaptic responses to glutamatergic input indicative of AMPA receptor–dependent transmission. This observation suggests that AMPA receptors are expressed ubiquitously and uniformly throughout the central nervous system. However, although widespread, quantitative autoradiography experiments utilizing [^3H]AMPA have demonstrated a heterogeneous distribution pattern. More specifically, high levels of AMPA receptors are expressed in the hippocampal formation and the outer layers of the cerebral cortex and the dorsal lateral septum. Intermediate concentrations are observed in the striatum and deep layers of the cerebral cortex. Lower levels of expression are found in thalamic nuclei and most midbrain and brain stem regions [65]. Consistent with these findings, *in vitro* quantitative autoradiography studies using radiolabeled versions of selective AMPA receptor agonists (e.g., (*S*)-[^3H]-5-fluorowillardiine, or [^3H]FW) and competitive antagonists (e.g., 6-[^3H]nitro-7-sulphamoylbenzo[*f*]-quinoxaline-2,3-dione, or [^3H]NBQX) have revealed binding distributions similar to that of [^3H]AMPA [66–70].

10.1.5 Kainate Receptors

Kainate receptors are comprised of members of two subunit families, $\text{GLU}_{\text{K}5-7}$ and $\text{GLU}_{\text{K}1-2}$ (GluR5–7 and KA1 and KA2) [43]. Although the $\text{GLU}_{\text{K}1}$ and $\text{GLU}_{\text{K}2}$ subunits bind kainate with high affinity, they do not appear to form functional ion channels when expressed as homomers in host cells. However, they do appear to form heteromeric receptors with the $\text{GLU}_{\text{K}5-7}$ subunits. $\text{GLU}_{\text{K}5-7}$ can form homomeric receptors in recombinant systems although it is likely that native receptors are heteromers. Splice variants exist for $\text{GLU}_{\text{K}5-7}$, adding another layer of potential heterogeneity for native kainate receptors. For individual subunits, KA receptors appear to share a topographical structure similar to that described for NMDA and AMPA receptors (Fig. 10.2).

Kainate receptors are broadly distributed throughout the mammalian nervous system (reviewed by Huettner [71]). They are localized on neuronal dendrites and postsynaptic membranes as well as on nerve fibers and synaptic terminals. In general, kainate receptors play an excitatory role, existing on the postsynaptic membranes of excitatory neurons. Presynaptic kainate receptors may also modulate the release of γ -aminobutyric acid (GABA) from inhibitory neurons [71, 72].

Kainate receptors are found within both the peripheral and central nervous systems. One of the earliest observations of kainate receptor-mediated responses was the depolarization of dorsal root fibers by kainate [1, 73]. Subsequent studies have indicated the presence of kainate receptors in both dorsal root ganglion neurons and spinal cord, in particular $\text{GLU}_{\text{K}5}$ [74]. Functional kainate receptors have also been demonstrated within spinal neurons [75–77].

Other areas of prominent kainate receptor expression within the central nervous system include the basal ganglia [78], basolateral amygdala [79], sensory cortex [80], striatum [81], hippocampus (both pre- and postsynaptically) [82, 83], hypothalamus ($\text{GLU}_{\text{K}5}$ and $\text{GLU}_{\text{K}6}$) [84], and the Purkinje cells [85] and granule cell layer ($\text{GLU}_{\text{K}2}$, $\text{GLU}_{\text{K}5}$, and $\text{GLU}_{\text{K}6}$) [86, 87] of the cerebellum. Kainate receptors have also been identified in retina [88].

Kainate receptors have been implicated to play a role in certain forms of epilepsy. Kainate administration causes a well-characterized seizure syndrome in rodents, which is associated with hippocampal neurodegeneration [89, 90]. $\text{GLU}_{\text{K}6}$ knock-out mice have been shown to be resistant to kainate-evoked seizures [91]. $\text{GLU}_{\text{K}5}$ kainate receptors have also been suggested to play a role in seizures. In rats, $\text{GLU}_{\text{K}5}$ selective antagonists have been shown to prevent pilocarpine-induced limbic seizures [92].

Kainate receptors may be in pathways responsible for anxiety. Although at the present time this area of kainate receptor function has yet to be extensively explored, the mixed AMPA–kainate receptor antagonist 3*S*,4*aR*,6*R*,8*aR*-6-(2-(1(2)*H*-tetrazol-5-yl)ethyl)-decahydroisoquinoline-3-carboxylic acid (LY293558) has been shown to produce anxiolytic-like effects in some animal models [93, 94]. Based on the binding profile of LY293558 [95, 96] and other pharmacological data [94, 97], $\text{GLU}_{\text{K}5}$ -containing kainate receptors have been hypothesized to be responsible for these anxiolytic-like behavioral effects [94]. The putative role of kainate receptors in anxiety could be related to the ability of kainate receptor activation to produce an enduring enhancement of excitatory synaptic responses in the basolateral amygdala [79].

A body of evidence has been accumulated indicating that kainate receptors containing $\text{GLU}_{\text{K}5}$ subunits also play a role in pain signaling. Kainate receptor antagonists selective for $\text{GLU}_{\text{K}5}$ have been shown to be active in animal models of inflammatory hyperalgesia, peripheral neuropathy, persistent pain, and migraine [98–101]. The mixed AMPA–kainate receptor antagonist LY293558 has also been found to reduce capsaicin-evoked [102] or postoperative [103] pain as well as migraine pain [104] in humans. It is interesting to note that, while LY293558 reduces the pain associated with these pathophysiological conditions, it does not affect normal pain sensation [102]. The presence of $\text{GLU}_{\text{K}5}$ kainate receptor subunits on trigeminal neurons [105] may explain the efficacy of $\text{GLU}_{\text{K}5}$ antagonists in migraine. It is currently unknown whether the other analgesic effects of $\text{GLU}_{\text{K}5}$ antagonists are mediated by central and/or peripherally located kainate receptors.

10.2 ORTHOSTERIC PHARMACOLOGICAL AGENTS

10.2.1 NMDA Receptor Orthosteric Agonists

Although less potent in most biological studies because of its rapid uptake by transporter systems, the natural ligand L-glutamate (Fig. 10.3) has about 10-fold greater affinity for the receptor than NMDA itself. L-Aspartate (Fig. 10.3), the other potentially natural ligand for the NMDA receptor, is less selective than NMDA and is also a substrate for transport systems. Quinolinic acid, another endogenous ligand, is weaker still. Thus, because of its superior selectivity and its lack of affinity for the transporter systems, NMDA has maintained its position as the prototypical agonist for this receptor, despite both an affinity in the 10 μ M range and not being quite a full agonist. Of the older agonists, only ibotenic acid (Fig. 10.3) mimicked the sensitivity of NMDA to a panel of antagonists [2], but ibotenate displayed an inhibitory second phase, possibly due to its conversion to muscimol by endogenous enzymes [106]. Ibotenic acid has an isoxazole bioisostere for the terminal carboxyl of L-glutamate and retains a similar affinity to the natural ligand. Inorganic terminal amino acid replacements (e.g., phosphonate, phosphinate, sulfonate), however, showed no improvement over the carboxyl of L-glutamate. Interestingly, replacing this with a tetrazole (tetrazolylglycine; Fig. 10.3) led to an approximately 10-fold increase in potency with maintained selectivity for the NMDA receptor [107, 108].

Further increases in potency were obtained by conformational restriction of the open chain of glutamate. Thus the 2*S*,1'*R*,2'*S* enantiomer of cyclopropylglutamate (CCG; Fig. 10.3) has an affinity in the 10-nM range [109] and *trans*-aminocyclobutanedicarboxylate (ACBD; Fig. 10.3) in the 100-nM range [110] similar to that of tetrazolylglycine [108]. Despite improved potency, these agonists have not become popular replacements for NMDA in pharmacological studies, presumably because of the more difficult synthesis and hence reduced availability.

The above glutamate site agonists act promiscuously at all the GLU_{N2} subtypes and no appreciable subtype selectivity has been reported. Homoquinolinic acid (Fig. 10.3), in which the amino group is incorporated into a pyridine ring, does, however, show such preferential selectivity for GLU_{N2B} subunits [47, 48], although the selectivity may not be so great at human GLU_{N2} subtypes [111].

10.2.2 NMDA Receptor Orthosteric Antagonists

Pharmacologically useful NMDA antagonists were initially developed by replacing the terminal carboxylate of D- α -amino adipate with a phosphonate to make D-2-amino-5-phosphonopentanoate (D-AP5; originally known as D-APV) [24] and by extending the chain length by two carbons to make D-2-amino-7-phosphonoheptanoate (Fig. 10.4; D-AP7). Interestingly compounds with intermediate lengths of this carbon backbone, as in D-AP4, D-AP6, and D-AP8, were relatively inactive as NMDA antagonists [24]. Compounds with the terminal amino acid of D-AP5 and D-AP7 replaced with a tetrazole and a carboxyl moiety still retain antagonist activity but the α -carboxyl cannot be replaced by phosphonate. The discovery of D-AP5 and D-AP7 catalyzed a large number of experiments to investigate the physiological and pathological functions of the NMDA receptor. For example, D-AP5 was used to determine the role of NMDA receptors in synaptic transmission and in long-term

Figure 10.4 NMDA receptor orthosteric antagonists.

potentiation (LTP) [7, 25], later shown to translate into memory defects in vivo [112]. D-AP5 and D-AP7 were shown to reduce neuronal cell death in animal models of cerebral ischaemia [26, 113] and reduce convulsions initiated in a number of different ways [26, 27] (see also [30]).

These compounds, however, only accessed the central nervous system poorly because of their polar nature—a severe limitation on their usefulness in behavioral and other in vivo studies and for therapeutic utility. In an attempt to improve blood–brain barrier penetration, by decreasing polarity and improving potency, many structurally constrained molecules were made, particularly by pharmaceutical companies (see [114, 115]). Thus, about an order-of-magnitude increase in potency over D-AP5 was achieved by introducing a double bond (CGP 37849; Fig. 10.4) [116] or a keto group (MDL 100453; Fig. 10.4 [117] or heteroatoms [118] into the carbon backbone. However, to achieve brain penetration following oral administration, esterification of the α -carboxyl of CGP 37849 was needed [116]. Further constraint of the carbon chain was gained by including the α -carboxyl of D-AP5 and D-AP7 in a piperidine (CGS19755 and CPPP; Fig. 10.3) [119] or piperazine (CPP; Fig. 10.4) [120] ring structure. Again the inclusion of a double bond or keto group improved potency as in CPP-ene (Fig. 10.4) [121] or MDL 100925 [122], respectively. The ultimate in structural constraint was achieved by incorporating a second ring into CPP. The resultant compound, LY235959 (Fig. 10.4), is among the most potent competitive NMDA receptor antagonists reported with an affinity in the 10nM range, approximately 100-fold more potent than the parent, AP7 [123, 124]. Biphenyl side chains have also been substituted in the D-AP7 molecule, for example SDZ-EAB-515 (Fig. 10.4), resulting in potent compounds with increased bioavailability and reasonable potency.

Several of the above compounds have been in development as potential therapies for epilepsy, [e.g., CPPene (SDZ-EAA-494)] and for stroke [e.g., CGS19755 (Selfotel)], but none are still in clinical development [29]. There have been a number of issues relating to dose levels, timing of the first treatment for stroke, and particularly appearance of adverse central nervous system side effects which, coupled with lack of efficacy in the outcomes measured, have led to the withdrawal of these compounds (see [28, 125]). It is generally assumed that these compounds show little if any selectivity between $\text{GLU}_{\text{N}2}$ subtypes. It has been reported, however, that D-CPPene shows preference for $\text{GLU}_{\text{N}2\text{A}}$ and $\text{GLU}_{\text{N}2\text{B}}$ over $\text{GLU}_{\text{N}2\text{C}}$ and $\text{GLU}_{\text{N}2\text{D}}$, whereas SDZ-EAB-515 and PBPD (Fig. 10.4) are less active on the $\text{GLU}_{\text{N}2\text{A}}$ subtype [48]. This selectivity correlates with the regional variation in antagonist affinity and the known distribution of $\text{GLU}_{\text{N}2}$ subtypes [48]. The competitive antagonist CPP displays a 50-fold selectivity for $\text{GLU}_{\text{N}2\text{A}}$ over $\text{GLU}_{\text{N}2\text{D}}$ but only 6- to 7-fold selectivity for $\text{GLU}_{\text{N}2\text{A}}$ over $\text{GLU}_{\text{N}2\text{B}}$ [126]. The longer chain antagonists such as CPP have been shown to display greater selectivity for $\text{GLU}_{\text{N}2\text{A}}$ over $\text{GLU}_{\text{N}2\text{C}}$ or $\text{GLU}_{\text{N}2\text{D}}$ than the shorter chain antagonists such as D-AP5 or CGS19755 [126]. A new compound, PEAQX, or AAM077 (Fig. 10.4), is claimed to show a 100-fold selectivity for human $\text{GLU}_{\text{N}2\text{A}}$ over $\text{GLU}_{\text{N}2\text{B}}$ [127]. However, when tested on rat subunits the selectivity was shown to be only 10-fold for $\text{GLU}_{\text{N}2\text{A}}$ over $\text{GLU}_{\text{N}2\text{B}}$ and 2- to 3-fold for $\text{GLU}_{\text{N}2\text{A}}$ over $\text{GLU}_{\text{N}2\text{C}}$ or $\text{GLU}_{\text{N}2\text{D}}$ [49]. Additionally, a recent report, suggests that the order of antagonist/agonist application affects the apparent subunit selectivity of this compound [128]. Recently, two compounds, PPDA and UBP141 (Fig. 10.4), have been reported to show 3- to 7-fold selectivity for $\text{GLU}_{\text{N}2\text{D}}$ over $\text{GLU}_{\text{N}2\text{A}}$ [49, 129].

These compounds have the reverse selectivity ($\text{GLU}_{\text{N2C}}/\text{GLU}_{\text{N2D}}$ over $\text{GLU}_{\text{N2A}}/\text{GLU}_{\text{N2B}}$) compared to the majority of competitive NMDA receptor antagonists, which show $\text{GLU}_{\text{N2A}}/\text{GLU}_{\text{N2B}}$ selectivity.

In contrast to their effects at the polyamine site, conantokin-G peptide, antagonism of NMDA receptors has also been suggested to be via the glutamate recognition site, with a strong preference for GLU_{N2B} subunit containing receptors [130].

10.2.3 AMPA Receptor Orthosteric Agonists

AMPA and analogs: A large number of orthosteric agonists of AMPA receptors have been described and many of them have been derived from classic structure–activity relationship studies using AMPA as a lead molecule (Fig. 10.5) [131]. A variety of analogs of AMPA having different substituents in the 5 position of the isoxazole ring have been synthesized which exhibit potent agonist properties, including the trifluoro AMPA and the phenyl derivative (*S*)-2-amino-3-(3-hydroxy-5-phenyl-4-isoxazolyl) propionic acid [(*S*)APPA] (for review see [132]). Additional AMPA analogs include the phenyl carboxy derivative (*R,S*)-2-amino-3-(3-carboxy-5-methyl-4-isoxazolyl) propionic acid [ACPA] [133] and 4-AHCP [134].

Willardiines and natural products: Another structurally distinct class of AMPA receptor agonists originates from willardiine. Among the willardiine agonists, a series of 5-substituted (*S*)-willardiines have been evaluated at native AMPA receptors on hippocampal neurons and display a rank order potency of fluoro > cyano = trifluoromethyl = nitro > chloro = bromo > (*R,S*)-AMPA > iodo > willardiine [135]. In addition to their activity at AMPA receptors, some willardiine derivatives (e.g., 5-iodowillardiine) also display potent activity at kainate receptors [135].

Naturally occurring neurotoxins such as domoic acid, a rigid analog of glutamate originally isolated from the macroscopic red alga *Chondria armata* (known in Japan as domoi), also have been shown to be potent agonists of AMPA receptors [136]. As well, kainic acid isolated from the dinoflagellate *Digenea simplex*, in addition to its agonist activity at kainate receptors, is an agonist of AMPA receptors [137, 138]. Both of these compounds are also agonists of kainate receptors and are discussed in greater detail below.

AMPA receptor agonists display a wide range of peak, steady-state whole-cell currents that are also reflected in corresponding single-channel currents. For example, saturating concentrations of glutamate and AMPA evoke large inward currents that desensitize rapidly to levels $\leq 10\%$ of the peak current depending on the receptor subtype [62, 63, 139, 140]. In contrast, kainate and domoate produce smaller

Figure 10.5 AMPA receptor orthosteric agonists.

peak currents and desensitize to levels substantially less ($\sim 70\%$ of peak current) than AMPA or glutamate [137, 138, 141]. Similarly, single-channel analyses have shown that kainate elicits significantly smaller currents than glutamate or AMPA, confirming its partial agonist nature at AMPA receptors [142]. The structural basis for differences between full and partial agonists has been elucidated in crystallographic studies analyzing the LBC of GLU_{A2} in the presence of glutamate, AMPA, and kainate [55]. The extent of agonism was shown to be directly related to the degree of closure of the upper and lower domains of the LBC such that full agonists induce greater domain closure than partial agonists. Functionally, the intermediate domain closure of kainate likely leads to a partial conformational change at the channel gate. Differences in the degree of desensitization between full and partial agonists are predicted to arise from differences in the extent of domain closure which affects the degree of intersubunit dimerization [55].

10.2.4 AMPA Receptor Orthosteric Antagonists

Quinoxalines: The first potent competitive antagonists of AMPA receptors were quinoxaline analogs, including 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX) and 6,7-dinitro-quinoxaline-2,3-dione (DNQX) (Fig. 10.6) [143, 144]. Although these compounds were not selective, having antagonist activity at the glycine binding site on NMDA receptors [145], they were prototypes for additional quinoxaline antagonists lacking the glycine site interaction, such as 2,3-dihydroxy-6-nitro-7-sulfamoylbenzo(f)quinoxaline (NBQX) [146]; 1,4,7,8,9,10-hexahydro-9-methyl-6-nitropyrido[3,4-*f*]-quinoxaline-2,3-dione (PNQX); 6-(1*H*-imidazol-1-yl)-7-nitro-2,3(1*H*,4*H*)-quinoxalinedione (YM-90K; Fig. 10.6) [147]; [2,3-dioxo-7-(1*H*-imidazol-1-yl)-6-nitro-1,2,3,4-tetrahydro-1-quinoxaliny]-acetic acid (YM872) [148]; and [1,2,3,4-tetrahydro-7-morpholinyl-2,3-dioxo-6-(trifluoromethyl)quinoxalin-1-yl]methylphosphonate (ZK200775) [149]. However, these newer compounds (as well as the older quinoxalines) also antagonize kainate receptors with varying degrees of selectivity for AMPA receptors, ranging from 3- to 10-fold [150].

Decahydroisoquinolines: Recently, other competitive antagonists belonging to the class of decahydroisoquinoline compounds have been discovered [151]. For example, LY293558 was shown to selectively displace ^3H -AMPA and ^3H -CNQX binding to rat brain membranes and potently antagonize AMPA-evoked depolarizations in rat cortical slices in a competitive manner (see Fig. 10.8 below) [95]. However, similar to the quinoxalines, the degree of selectivity for AMPA receptors versus kainate receptors of decahydroisoquinolines can vary considerably [96, 151–153]. For instance, LY293558 binds with equal affinity to AMPA ($K_D = 3.3 \mu\text{M}$) and kainate ($K_D = 4.9 \mu\text{M}$) receptors, whereas LY382884 binds with at least 100-fold greater

Figure 10.6 AMPA receptor orthosteric antagonists.

affinity to kainate ($K_D = 3.6 \mu\text{M}$) versus AMPA ($K_D = 550 \mu\text{M}$) receptors [153]. Other decahydroisoquinolines show slight selectivity for AMPA receptors. For instance, LY302679 is approximately fourfold selective for AMPA ($K_i = 0.8 \mu\text{M}$) versus kainate ($K_i = 3.4 \mu\text{M}$) receptors [153].

An understanding of the mechanism of orthosteric antagonism of AMPA receptors has come from crystal structures of the AMPA receptor LBC in the presence of DNQX [55]. These studies showed that competitive antagonists act by preventing closure of the two domains of the LBC. Indeed, although not identical, the degree of domain closure of the LBC in the DNQX crystals is quite similar to that observed in the agonist unbound apo state crystals. Thus, in the presence of a competitive antagonist, stabilization of the “open” configuration of the two domains of the LBC is predicted to preclude a directed conformational change at the channel gate [55].

10.2.5 Kainate Receptor Orthosteric Agonists

Glutamate: Glutamate, the endogenous ligand, activates kainate receptor channels with median effective concentration (EC_{50}) values at recombinant human kainate receptors ranging from approximately $10 \mu\text{M}$ for GLU_{K6} and $\text{GLU}_{K2}/\text{GLU}_{K6}$, to $\sim 50 \mu\text{M}$ for GLU_{K5} and $\text{GLU}_{K5}/\text{GLU}_{K6}$ [97]. Glutamate exhibits much lower affinity for GLU_{K7} ($EC_{50} = 6 \text{ mM}$ [154]). Obviously, glutamate is not selective for kainate receptors as it also activates all other ionotropic and metabotropic glutamate receptors.

Gamma glutamate analogs: The gamma-substituted glutamate analog (2*S*,4*R*)-4-methylglutamate (SYM2081) has been studied at GLU_{K5} - and GLU_{K6} -containing channels. SYM2081 activates these channels with sub-micromolar (0.06 – $0.4 \mu\text{M}$) potency (Fig. 10.7) [97]. SYM2081 produces pronounced desensitization and acts as a functional antagonist with prolonged application. Presumably because of its ability

Figure 10.7 KA receptor orthosteric agonists.

TABLE 10.1 Agonist Potency at Recombinant Human GLU_{K5}- and GLU_{K6}-Containing Kainate Receptors

Agonist	GLU _{K5}	GLU _{K6}	GLU _{K5} /GLU _{K6}	GLU _{K2} /GLU _{K5}	GLU _{K2} /GLU _{K6}
Glutamate	47	9	48	19	8
Kainate	5	1	7	2	0.6
SYM2081	0.2	0.3	0.4	0.06	0.3
Domoate	0.4	0.07	0.2	0.05	0.1
AMPA	208 ^a	NA (1 mM)	154 ^a	123 ^a	137 ^a
ATPA	0.3	NA (0.1 mM)	0.8	0.4	106 ^a
Iodowillardiine	0.2	NA (1 mM)	0.5	0.06	30 ^a

Note: Values given represent EC₅₀ (in μ M) determined in the presence of concanavalin A.

Source: From [97].

^aPartial agonist. NA = no agonist activity observed (up to the concentration listed).

to functionally antagonize GLU_{K5} channels, SYM2081 produces antagonist-like antinociceptive responses in animal models of nerve injury [155]. SYM2081 is selective for kainate versus AMPA receptors but does not display pharmacological selectivity between GLU_{K5} and GLU_{K6} receptors (Table 10.1) [97, 156]. SYM2081 also exhibits agonist activity at NMDA receptors (EC₅₀ = 12 μ M at NMDA receptors expressed natively in cultured rat hippocampal neurons [156]).

Related analogs such as (2*S*,4*R*,6*E*)-2-amino-4-carboxy-7-(2-naphthyl)hept-6-enoic acid (LY339434) show improved selectivity for GLU_{K5} versus GLU_{K6} receptors (Fig. 10.7) [156]. LY339434 was found to evoke inward currents at recombinant human GLU_{K5} with EC₅₀ = 2.5 μ M but had little effect at GLU_{K6} at concentrations less than 100 μ M [156]. Like SYM2081, LY339434 shows low potency at AMPA receptors (EC₅₀ > 300 μ M) but is a potent agonist at NMDA receptors (EC₅₀ = 2.5 μ M at NMDA receptors expressed natively in cultured rat hippocampal neurons [156]). Related alkylidene glutamate analogs also are potent GLU_{K5} agonists with increased binding affinity produced by the introduction of lipophilic 4-alkylidene groups. In contrast, potencies of these agonists at GLU_{K6} receptors were decreased by this functional group [157].

The selectivity of the γ -glutamate analogs for GLU_{K5} versus GLU_{K6} receptors has been used to provide evidence that the kainate receptors expressed in cultured hippocampal rat neurons represent primarily GLU_{K6} receptors [158].

Marine products: Kainate is derived from the seaweed *D. simplex*. Domoate, another kainate receptor agonist, originates from the related seaweed *C. armate* (Fig. 10.7). Both compounds are potent neurotoxins. Kainate activates GLU_{K5} and GLU_{K6} receptors with EC₅₀ values in the low (\sim 1–10) micromolar range. Domoate is more potent, with EC₅₀ values ranging from \sim 0.05 to 0.4 μ M [97]. Like glutamate, kainate is able to activate GLU_{K7} receptors, but with extremely low (millimolar range) potency, while domoate is not active at GLU_{K7} [154]. Both of these agonists also evoke non-desensitizing responses at AMPA receptors, limiting their use as kainate-selective ligands. However, low concentrations of domoate (0.2 μ M) have been used to selectively activate kainate receptors [159]. Interestingly, domoate-evoked activation of kainate receptor channels appears to be less subject to desensitization than that produced by other kainate receptor agonists. Therefore, domoate has been used in the

absence of concanavalin A in assays which typically require the use of the lectin (or another blocker of desensitization) in order to observe agonist effects [160].

Dysiherbaine, another potent neuroexcitotoxin, was isolated from the Micronesian sponge *Dysidea herbacea* (Fig. 10.7) [161]. In rat brain synaptic membranes, dysiherbaine was found to displace [^3H]kainate and [^3H]AMPA binding with K_i values of 26 and 153 nM, respectively [162]. Dysiherbaine did not displace the binding of the NMDA receptor ligand [^3H]CGS-19755. Dysiherbaine displaced [^3H]kainate at recombinant rat kainate receptors with higher affinity than was observed in native tissues, with K_i values of 4, 0.5, and 1 nM at recombinant rat $\text{GLU}_{\text{K}2}$, $\text{GLU}_{\text{K}5}$, $\text{GLU}_{\text{K}6}$, respectively [163]. In whole-cell voltage clamp recordings from cultured rat hippocampal neurons, dysiherbaine evoked inward currents from both kainate and AMPA receptors with EC_{50} values of 0.2 and 9.7 μM , respectively. In calcium imaging experiments, it was found that dysiherbaine also activated the group I metabotropic receptor mGluR5 [162]. Dysiherbaine appears to bind to $\text{GLU}_{\text{K}2}$ subunits with lower affinity than $\text{GLU}_{\text{K}5}$ or $\text{GLU}_{\text{K}6}$ subunits and has been used to provide evidence that kainate receptor current may be gated by individual subunits [164].

Neodysiherbaine (Fig. 10.7) is a natural analog of dysiherbaine that is produced by *D. herbacea* in much lower quantities [165]. Like dysiherbaine, neodysiherbaine is an agonist at both kainate and AMPA receptors [163]. In radioligand binding assays using recombinant rat receptors, neodysiherbaine displaced [^3H]kainate with 7-fold higher affinity than dysiherbaine at $\text{GLU}_{\text{K}2}$ receptors but displayed 15- to 25-fold lower affinity than dysiherbaine at $\text{GLU}_{\text{K}5}$ and $\text{GLU}_{\text{K}6}$ receptors (K_i values of 0.6, 7.7, and 33 nM for neodysiherbaine at $\text{GLU}_{\text{K}2}$, $\text{GLU}_{\text{K}5}$, and $\text{GLU}_{\text{K}6}$ receptors, respectively [163]). Neodysiherbaine shows no affinity for NMDA receptors [165], and, unlike dysiherbaine, neodysiherbaine shows no agonist activity at mGluR5 receptors [163].

The synthetic dysiherbaine analog (2*R*,3*aR*,7*aR*)-2-[(2*S*)-2-amino-2-carboxyethyl]-hexahydro-furo[3,2-*b*]pyran-2-carboxylic acid (MSVIII-19) can act as a functional antagonist (a desensitizing agonist) at $\text{GLU}_{\text{K}5}$ receptors and, with much lower affinity, AMPA receptors [163]. MSVIII-19 displaced [^3H]kainate from recombinant rat $\text{GLU}_{\text{K}5}$ with $K_i = 0.1 \mu\text{M}$. MSVIII-19 displays no appreciable affinity for $\text{GLU}_{\text{K}2}$ or $\text{GLU}_{\text{K}6}$ receptors ($K_i > 100 \mu\text{M}$) [163].

Willardiines: (S)-1-(2-Amino-2-carboxyethyl)pyrimidine-2,4-dione, or (S)-willardiine, occurs naturally in the seeds of several species of shrub trees [166]. Willardiine and a series of 5-substituted (S)-willardiine analogs were discovered to act as agonists at AMPA and kainate receptors [167]. Their rank order of potency in rat dorsal root ganglia (DRG) neurons, a $\text{GLU}_{\text{K}5}$ -containing preparation, is trifluoromethyl ($\text{EC}_{50} = 70 \text{ nM}$) > iodo > bromo \approx chloro > nitro \approx cyano > methyl > fluoro \gg willardiine ($\text{EC}_{50} = 69 \mu\text{M}$) [135]. In addition to differences in their potency and selectivity for $\text{GLU}_{\text{K}5}$ versus AMPA receptors, these willardiine analogs also vary dramatically in their desensitization kinetics ($\tau_{\text{off}} = 43 \text{ ms}$ for 5-fluoro versus 4.2 s for 5-iodo).

Of the willardiine analogs, (S)-5-iodowillardiine has been the most extensively studied. (S)-5-Iodowillardiine displays 100- to 1000-fold selectivity for $\text{GLU}_{\text{K}5}$ versus AMPA receptors (Fig. 10.7) [135, 168] and shows no appreciable activity at recombinant human homomeric $\text{GLU}_{\text{K}6}$ or $\text{GLU}_{\text{K}7}$ receptors [97, 169]. Interestingly, (S)-5-iodowillardiine has been shown to function as a partial agonist at heteromeric $\text{GLU}_{\text{K}2}/\text{GLU}_{\text{K}6}$ [97, 169] or $\text{GLU}_{\text{K}2}/\text{GLU}_{\text{K}7}$ [142] receptors. More recently, a

number of willardiine derivatives which act as competitive $\text{GLU}_{\text{K}5}$ antagonists have also been identified (discussed below).

AMPA and ATPA: In addition to potently activating AMPA receptors, AMPA also activates $\text{GLU}_{\text{K}5}$ -containing channels. Alt et al. [97] reported that AMPA functions as a partial agonist at recombinant human homomeric $\text{GLU}_{\text{K}5}$ and heteromeric $\text{GLU}_{\text{K}5}/\text{GLU}_{\text{K}6}$ and $\text{GLU}_{\text{K}2}/\text{GLU}_{\text{K}5}$ kainate receptors with EC_{50} values of 0.1–0.2 mM. Like (*S*)-5-iodowillardiine, AMPA has no effect at homomeric $\text{GLU}_{\text{K}6}$ receptors but displays partial agonist activity at recombinant human $\text{GLU}_{\text{K}2}/\text{GLU}_{\text{K}6}$ receptors ($\text{EC}_{50} = 30 \mu\text{M}$ [97]).

The *tert*-butyl analog of AMPA, (*R,S*)-2- α -amino-3-hydroxy-5-*tert*-butyl-4-isoxazolepropionic acid (ATPA), was originally developed as an AMPA receptor agonist. ATPA has greater brain penetration than AMPA but has lower affinity for AMPA receptors (Fig. 10.7) [170]. Using cell lines stably expressing recombinant human glutamate receptors, Clarke et al. [152] found that ATPA binds selectively to $\text{GLU}_{\text{K}5}$ ($K_i = 4.3 \text{ nM}$) versus $\text{GLU}_{\text{A}1-4}$ (K_i values of 6–14 μM), $\text{GLU}_{\text{K}2}$ or $\text{GLU}_{\text{K}7}$ ($K_i > 10 \mu\text{M}$), or $\text{GLU}_{\text{K}6}$ or heteromeric $\text{GLU}_{\text{K}2}/\text{GLU}_{\text{K}6}$ ($K_i > 1 \text{ mM}$) receptors. In whole-cell recordings, ATPA evoked inward currents at $\text{GLU}_{\text{K}5}$ ($\text{EC}_{50} = 2 \mu\text{M}$) and AMPA (EC_{50} values of 0.4–0.7 mM) receptors but showed no agonist activity at $\text{GLU}_{\text{K}6}$ receptors at concentrations up to 10 mM [152]. Alt et al. [97] reported similar EC_{50} values for ATPA for evoking calcium influx through recombinant human $\text{GLU}_{\text{K}5}$, $\text{GLU}_{\text{K}2}/\text{GLU}_{\text{K}5}$, or $\text{GLU}_{\text{K}5}/\text{GLU}_{\text{K}6}$ receptors ($\text{EC}_{50} = 0.3\text{--}0.8 \mu\text{M}$) or for evoking inward currents at recombinant human $\text{GLU}_{\text{K}5}$ or $\text{GLU}_{\text{K}5}/\text{GLU}_{\text{K}6}$ ($\text{EC}_{50} = 1 \mu\text{M}$) or $\text{GLU}_{\text{K}5}$ receptors natively expressed in rat DRG ($\text{EC}_{50} = 0.4 \mu\text{M}$). Additionally, in a calcium influx assay, ATPA was found to function as a partial agonist at heteromeric $\text{GLU}_{\text{K}2}/\text{GLU}_{\text{K}6}$ receptors ($\text{EC}_{50} = 0.1 \text{ mM}$), and it was demonstrated that ATPA partially antagonized the agonist effects of glutamate at these channels. Similarly, at homomeric $\text{GLU}_{\text{K}6}$ receptors, where ATPA showed no agonist activity, it was found that ATPA was able to block calcium influx evoked by glutamate, which would seemingly indicate that ATPA does in fact bind to $\text{GLU}_{\text{K}6}$ receptors, albeit with low affinity (median inhibitory concentration $\text{IC}_{50} \sim 2 \text{ mM}$, corresponding to a K_b of approximately 0.2 mM [97]).

10.2.6 Kainate Receptor Orthosteric Antagonists

Oxime derivatives: One of the first compounds identified as a kainate receptor antagonist was the oxime derivative 5-nitro-6,7,8,9-tetrahydrobenzo[g]indole-2,3-dione-3-oxime (NS102; Fig. 10.8). It is a weak antagonist at $\text{GLU}_{\text{K}6}$ receptors [171]. It also antagonized $\text{GLU}_{\text{K}5}$ receptors expressed in rat DRG neurons ($K_b = 6 \mu\text{M}$ [172]). NS102 is also an AMPA receptor antagonist, blocking AMPA receptor-mediated responses in primary rat cortical cultures with $K_b = 114 \mu\text{M}$ [172].

Recently, another oxime derivative, 8-methyl-5-(4-(*N,N*-dimethylsulfamoyl)phenyl)-6,7,8,9-tetrahydro-1*H*-pyrrolo[3,2-*h*]-iso-quinoline-2,3-dione-3-*O*-(4-hydroxybutyric acid-2-yl)oxime (NS1209), has been shown to be effective in the mouse hot-plate test (an acute-pain model), the rat formalin test (a model of persistent pain), and the rat chronic constriction injury model of neuropathic pain [173]. However, NS1209 exhibits antagonist activity at both AMPA and $\text{GLU}_{\text{K}5}$ receptors (with approximately 30-fold selectivity for AMPA receptors [174]), making it difficult to conclude which receptor type mediated these pharmacological effects.

Figure 10.8 KA receptor orthosteric antagonists.

Quinoxalinediones: A number of quinoxaline derivatives have been discovered to function as both AMPA and kainate receptor antagonists. Wilding and Huettner [175] examined a series of these compounds and compared their ability to block inward currents evoked by kainate (which also activates AMPA receptors) in primary cultures of either rat DRG (a GLU_{K5} -containing preparation) or cortex (an AMPA receptor-containing preparation). Of the compounds tested, NBQX showed the greatest (3-fold) selectivity for AMPA receptors, while 5-chloro-7-trifluoromethyl-2,3-quinoxalinedione (ACEA-1011) displayed the greatest (12-fold) selectivity for kainate versus AMPA receptors. However, this compound exhibits even greater potency ($K_b = \sim 0.5 \mu\text{M}$ [176, 177]) at NMDA receptors than that observed for kainate receptors ($K_b = 1 \mu\text{M}$ [175]).

Of the quinoxalinediones, NBQX and CNQX are the most extensively studied, primarily as AMPA receptor antagonists, although both are also kainate receptor antagonists and CNQX is an antagonist at NMDA receptors. NBQX and CNQX block AMPA receptor-mediated responses in cortical preparation with K_b values of 0.3 and $1.3 \mu\text{M}$, respectively [175]. At kainate receptors, both NBQX and CNQX display little selectivity across kainate receptor subtypes [97]. The antagonist potencies for NBQX and CNQX at recombinant human kainate receptors are given in Table 10.2.

Decahydroisoquinolines: The first decahydroisoquinolines described were NMDA-selective antagonists [178]. In the course of structure-activity studies on this series, decahydroisoquinolines which functioned as AMPA receptor antagonists were identified [151]. LY293558 was the first decahydroisoquinoline discovered to have potent GLU_{K5} antagonist activity, in addition to functioning as an AMPA/NMDA

TABLE 10.2 Antagonist Potency at Recombinant Human GLU_{K5} - and GLU_{K6} -Containing Kainate Receptors

Antagonist	GLU_{K5}	GLU_{K6}	$\text{GLU}_{\text{K5}}/\text{GLU}_{\text{K6}}$	$\text{GLU}_{\text{K2}}/\text{GLU}_{\text{K5}}$	$\text{GLU}_{\text{K2}}/\text{GLU}_{\text{K6}}$

antagonist [95]. Although LY293558 shows virtually no selectivity for $\text{GLU}_{\text{K}5}$ versus AMPA receptors and modest (~ 10 -fold) selectivity for $\text{GLU}_{\text{K}5}$ versus NMDA receptors [179], it displays virtually complete selectivity for $\text{GLU}_{\text{K}5}$ versus $\text{GLU}_{\text{K}6}$ [96].

Other decahydroisoquinolines were subsequently discovered which exhibited even greater potency, such as LY377770 (Table 10.2). Others showed greatly improved selectivity for kainate versus AMPA receptors while maintaining selectivity for $\text{GLU}_{\text{K}5}$ versus $\text{GLU}_{\text{K}6}$. 3*S*,4*aR*,6*S*,8*aR*-6-((4-carboxyphenyl)methyl)-1,2,3,4,4*a*,5,6,7,8,8*a*-decahydroisoquinoline-3-carboxylic acid (LY382884) was found to inhibit radioligand binding to recombinant human $\text{GLU}_{\text{K}5}$ with $K_i = 4 \mu\text{M}$, while showing little or no affinity ($K_i > 100 \mu\text{M}$) for $\text{GLU}_{\text{A}1-4}$, $\text{GLU}_{\text{K}2}$, $\text{GLU}_{\text{K}6}$, $\text{GLU}_{\text{K}7}$, or a heteromeric assembly of $\text{GLU}_{\text{K}2}/\text{GLU}_{\text{K}7}$. Additionally, LY382884 had little activity at NMDA receptors, producing only a small effect at $300 \mu\text{M}$ [180]. Like other $\text{GLU}_{\text{K}5}$ -selective antagonists, LY382884 has also been found to be a potent antagonist of heteromeric $\text{GLU}_{\text{K}5}/\text{GLU}_{\text{K}6}$ receptors [97, 180].

A great deal of evidence for the involvement of $\text{GLU}_{\text{K}5}$ receptors in pathophysiological pain states has come from experiments using decahydroisoquinolines. LY293558 was found to reduce capsaicin-evoked hyperalgesia in the skin of human subjects without affecting normal pain sensation [102]. LY293558 has also been found to reduce spontaneous and movement-evoked pain following oral surgery [103] and to reduce migraine pain in humans [102]. In rats, Simmons et al. [98] showed that LY382884 was efficacious in the formalin test, an animal model of persistent pain. Palacek et al. [100] found that LY382884 attenuated the responses of spinothalamic tract neurons to mechanical and thermal stimuli in a model of peripheral neuropathy using anesthetized monkeys.

Recent research on decahydroisoquinolines has focused on the creation of prodrug molecules with improved oral bioavailability. In this regard, ester prodrugs of decahydroisoquinolines have recently been shown to be orally active in animal models of migraine, inflammatory hyperalgesia, and persistent pain [99, 101].

Willardiine derivatives: As mentioned above, (*S*)-willardiine and a number of 5-substituted (*S*)-willardiine analogs act as agonists at AMPA and kainate receptors. The N^3 -substituted willardiine analog (*S*)-3-(4-carboxybenzyl)willardiine (3-CBW) was found to act as an antagonist at AMPA and kainate receptors, expressed in rat neuronal tissues [181]. 3-CBW (Fig. 10.8) antagonized kainate-induced responses on rat dorsal root C fibers (presumably $\text{GLU}_{\text{K}5}$ receptors) with $\text{pA}_2 = 4.96$ (corresponding to an apparent K_D of approximately $11 \mu\text{M}$) based on Schild plot analysis. The pA_2 value at AMPA receptors was 4.48 (corresponding to a K_D of approximately $33 \mu\text{M}$).

Structure-activity studies on this series led to the identification of compounds with greater potency and selectivity for kainate receptors versus AMPA receptors [182]. (*R,S*)-3-(2-Carboxybenzyl)willardiine (UBP296) was been identified as a member of this series which displayed very potent (approximately $1 \mu\text{M}$) affinity for $\text{GLU}_{\text{K}5}$ receptors, exhibited selectivity for kainate versus AMPA receptors, and showed no significant activity at NMDA receptors or group I metabotropic glutamate receptors (mGlu_1 or mGlu_5 [183]). UBP296 is very selective for $\text{GLU}_{\text{K}5}$ versus $\text{GLU}_{\text{K}6}$. The *S* enantiomer UBP302 was shown to have the predominant antagonist activity at native $\text{GLU}_{\text{K}5}$ kainate receptors ($K_D = 0.4 \mu\text{M}$) [183, 184]. In human embryonic kidney (HEK) 293 cells recombinantly expressing human kainate receptors, UBP296

antagonized 100 μM glutamate at homomeric $\text{GLU}_{\text{K}5}$ or heteromeric $\text{GLU}_{\text{K}2}/\text{GLU}_{\text{K}5}$ channels with K_{b} values of 0.6 and 1 μM , respectively, but had no effect at $\text{GLU}_{\text{K}6}$ or $\text{GLU}_{\text{K}2}/\text{GLU}_{\text{K}6}$ receptors at concentrations up to 300 μM (Table 10.2). Like other $\text{GLU}_{\text{K}5}$ -selective antagonists, UBP296 was an antagonist at heteromeric $\text{GLU}_{\text{K}5}/\text{GLU}_{\text{K}6}$ receptors with potency similar to that seen at homomeric $\text{GLU}_{\text{K}5}$ ($\text{GLU}_{\text{K}5}/\text{GLU}_{\text{K}6}$ at $K_{\text{b}}=0.8 \mu\text{M}$). UBP296 also exhibits low affinity binding to recombinant human $\text{GLU}_{\text{K}7}$, displacing [^3H]kainate with $K_{\text{i}}=0.9 \text{ mM}$ [184].

Kynurenic acid: A tryptophan metabolite, kynurenic acid is a low-affinity antagonist at AMPA, NMDA, and kainate receptors (Fig. 10.8) [185]. Kynurenic acid was found to block glutamate (100 μM)–evoked calcium influx through recombinant human kainate receptors with IC_{50} values of approximately 500 μM for $\text{GLU}_{\text{K}5}$, $\text{GLU}_{\text{K}5}/\text{GLU}_{\text{K}6}$, $\text{GLU}_{\text{K}2}/\text{GLU}_{\text{K}5}$, and $\text{GLU}_{\text{K}6}$ (Table 10.2) [97]. Interestingly, kynurenic acid had no discernable activity at the $\text{GLU}_{\text{K}2}/\text{GLU}_{\text{K}6}$ receptors at concentrations up to 3 mM.

GAMS: γ -D-Glutamylaminomethylsulfonic acid (GAMS) has been reported to act as an antagonist of both AMPA and kainate receptors (Fig. 10.8) [186, 187], but with a preference for kainate receptors ($K_{\text{D}} \sim 50 \mu\text{M}$ [188]). Wilding and Huettnner [172], however, did not observe a selectivity for kainate receptors and found GAMS to have low potency in DRG neurons ($K_{\text{b}}=360 \mu\text{M}$). Alt et al. [97] also found GAMS to exhibit low potency with IC_{50} values in the range of 1–2 mM (corresponding to K_{b} values of $\sim 300 \mu\text{M}$) at recombinant human $\text{GLU}_{\text{K}5}$, $\text{GLU}_{\text{K}2}/\text{GLU}_{\text{K}5}$, and $\text{GLU}_{\text{K}5}/\text{GLU}_{\text{K}6}$ receptors (Table 10.2). Although the activity observed at $\text{GLU}_{\text{K}5}$ -containing channels was weak, there appeared to be a degree of selectivity versus $\text{GLU}_{\text{K}6}$ since no antagonist effects were observed for GAMS at concentrations up to 3 mM at either $\text{GLU}_{\text{K}6}$ or $\text{GLU}_{\text{K}2}/\text{GLU}_{\text{K}6}$ receptors.

10.3 ALLOSTERIC POTENTIATORS AND ANTAGONISTS

10.3.1 NMDA Receptor Allosteric Potentiators

Agonists at the glycine binding site: In an initial series of studies, Johnson and Ascher [36] showed that glycine (Fig. 10.9) was an important coagonist at the NMDA receptor and that this activity could be mimicked by some other neutral amino acids including D-serine (Fig. 10.9) and D-alanine. Careful work by Kleckner and

Figure 10.9 NMDA receptor allosteric potentiators.

Dingledine [37] demonstrated that occupation of this glycine site was a necessary requirement for NMDA receptor activation. Nanomolar concentrations of glycine appeared to be sufficient to enable activation by glutamate or NMDA, and these were thought to be provided by the endogenous levels of extracellular glycine. Indeed initial studies in vivo and in vitro suggested that this glycine site was fully occupied and addition of exogenous glycine or D-serine did not enhance NMDA receptor function. More recent studies have, however, suggested that this is not the case, and so potentially positive and negative modulation of NMDA receptor efficiency via this glycine site appears to be feasible (see [189]).

Following the initial discovery of this action of glycine, several analogs of glycine were found to be active with varying degrees of partial agonism. Among these D-cycloserine (Fig. 10.9) is a weak partial agonist but nevertheless has apparently some benefit in schizophrenia patients, as do massive doses of glycine and D-serine (see [35]). One of the less efficacious partial agonists is HA-966 (Fig. 10.9), which acts as a glycine site antagonist in vivo [190], a finding which explains its previously described NMDA antagonism [22]. Partial agonist analogs of HA-966 that are 10 times more potent than the parent compound have been developed as functional antagonists (e.g., L-687,414; Fig. 10.9) [191].

Of the newly discovered fuller agonists, aminocyclopropylcarboxylic acid (ACC) [192] is the most potent with an affinity an order of magnitude higher than that of glycine and D-serine. However, D-serine remains a useful tool for this site since unlike glycine it is not an agonist at the strychnine-sensitive inhibitory receptor and less subject to uptake by neutral amino acid transporter systems.

Positive allosteric modulators of NMDA receptor function: Ransom and Stec [38] described the NMDA potentiating (and inhibiting) effects of polyamines such as spermine and spermidine. There appear to be two facets to this potentiation [8, 193]: first, an increase in affinity of the GLU_{N1} subunit for glycine and, second, a glycine-independent potentiation of NMDA receptors containing GLU_{N2B} subunits and dependent on the splice variant of GLU_{N1} lacking exon 5 [194, 195]. The action of these positively charged polyamines appears to be mimicked by certain aminoglycoside antibiotics [196] and by magnesium ions [197, 198].

Interestingly, steroid hormones, more widely recognized for enhancing GABA function, also potentiate NMDA receptor function. This appears to be subtype selective, inasmuch as pregnenolone enhances heteromers containing the GLU_{N2A} and GLU_{N2B} subunits but inhibits those containing GLU_{N2C} and GLU_{N2D} subunits [199]. This NMDA potentiating effect of polyamines can be reversed by the peptide conantokin-G, derived from *Conus* snails [200]. Structure–activity studies with peptide fragments and analogs from conantokin-G have elucidated molecules that potentiate [201] NMDA receptor function or act as polyamine antagonists [202].

10.3.2 NMDA Receptor Allosteric Antagonists

Competitive glycine site antagonists: The first functional glycine site antagonists reported were HA-966 (Fig. 10.9) [190] and kynurenic acid [203]. It was subsequently discovered that these two compounds act fundamentally differently; that is, HA-966 is a weak partial agonist whereas kynurenic acid is a full antagonist [204, 205]. Structure–activity studies of both compounds have produced more potent and selective analogs.

The (*R*)-(+) enantiomer of HA-966 is the active agent. One of the most potent of the HA-966 analogs yet developed is L-687,414 with affinity in the low-micromolar range [206]. This potentially useful pharmacological agent crosses the blood–brain barrier to provide functional antagonism *in vivo* as evidenced by its neuroprotective effect in focal ischemia [207] but interestingly did not block LTP *in vivo* as do classical NMDA antagonists [208]. Other partial agonists include cyclobutyl and cyclopropyl substituted glycines [192, 209, 210] as well as D-cycloserine [211], which, at higher doses, reverses the benefits in schizophrenia seen at lower doses (see [35]). This illustrates the difficulty of using partial agonists for *in vivo* studies, because at low concentrations they act as weak agonists but at higher concentrations will appear as antagonists.

Kynurenine acid is, by comparison, a full antagonist at the glycine site but is very nonspecific, with antagonist effects at other glutamate receptors. The usefulness of kynurenate analogs was, however, indicated by the observation that the 7-chloro and 5,7-dichloro derivatives (Fig. 10.10) were quickly shown to be more potent and selective glycine site antagonists [205, 212, 213]. Interestingly, the quinoxalinediones DNQX and CNQX [214] show weak glycine site antagonism [215], in addition to their more potent effects at the AMPA receptors. Kynurenates and quinoxalinediones, thus, formed the basis for the structure–activity studies for the development of full glycine site antagonists. Among the most potent of these are L-689,560 (Fig. 10.10) [216], L-701,324 (Fig. 10.9) [217], ACEA-1021 (Fig. 10.10) [218], GV150526 (Fig. 10.9) [219], and MRZ 2/576 (Fig. 10.9) [220]. In general, however, these compounds have poor bioavailability due to plasma protein binding (see [221]) but nevertheless have been shown to have typical NMDA antagonist profiles, for example, anticonvulsant, neuroprotective, and analgesic, but appear to have less psychotomimetic potential [191]. GV150526 was assessed in two large phase III trials for stroke; however, no positive outcome was seen. There remain questions over the brain bioavailability of this compound and the length of the time to treatment of the stroke patients.

Channel blocking NMDA antagonists: Magnesium ions are the physiological blockers of the NMDA channel [18], controlling channel conductance in a voltage-dependent manner [222, 223] such that depolarization from resting potential increases inward current in the presence of an NMDA receptor agonist. This “positive-feedback” phenomenon is dependent on the normal levels of extracellular magnesium and underlies the characteristic electrophysiological and pathological properties of NMDA receptor activation. Depolarization relieves the magnesium block and allows cationic current including calcium via the NMDA channel in circumstances such as repeated synaptic activation via afferent input or continuous activation via high levels of extracellular glutamate. Interestingly, the block by magnesium ions at a site deep within the channel is greater on complexes containing GLU_{N2A}/GLU_{N2B} subunits than those containing GLU_{N2C}/GLU_{N2D} [46]. Other divalent cations vary in their ability to permeate or block the NMDA receptor channel [224].

Ketamine and phencyclidine (Fig. 10.10) were discovered as NMDA antagonists [32] as part of a study into the central mechanisms of short-acting anaesthetics [225]. Ketamine was also shown to block the “wind-up” phenomenon of neuropathic pain which in part explains its analgesic properties [226]. Block of the NMDA receptor occurred, however, at doses that were considerably less than those needed for

Figure 10.10 NMDA receptor allosteric antagonists.

anaesthesia and which were rather similar to those inducing “psychotomimetic-like” effects in laboratory animals (see [227, 228]). It quickly became apparent that many other drugs inducing psychotomimetic behavior in humans and/or generalization to phencyclidine in animal studies shared NMDA antagonistic properties [33]. The list includes the sigma opiates, SKF10,047, cyclazocine, and pentazocine [229], dioxalones [230], the morphinans dextromethorphan and dextrorphan (Fig. 10.10) [231], and the dibenzocycloalkenimine MK-801 (Fig. 10.10) [232]. All these channel blocking compounds display voltage and use dependence; that is, they need activation of the receptor channel complex for both access to and dissociation from the NMDA channel and, where examined, produce schizophrenomimetic effects in humans [233–236] (see [35]). MK-801 is the most potent and selective and is used as a standard in many experimental assays. It is, however, atypical in that it has a long duration of action, in part due to its slow off time even in the presence of agonist and is therefore likely to have profound and long-lasting psychotomimetic effects in humans. At the other end of the spectrum is memantine (Fig. 10.10), which has fast “on-and-off” kinetics and a reduced tendency to psychotomimetic effects [237].

In addition to such pharmacodynamic differences, their good bioavailability, and the range of pharmacokinetic properties, several channel blocking compounds offer useful characteristics to preclinical and clinical researchers. Thus brief reversible or long-duration block of NMDA receptors can be achieved with ketamine or MK-801, respectively. Ketamine and dextromethorphan, approved for use in humans, have been used for exploring the effects of NMDA blockade in normal volunteers and psychiatric patients (see [35]). These allosteric NMDA antagonists mimic the symptoms of schizophrenia in humans, and hence enhancing NMDA receptor-mediated synaptic transmission, directly or indirectly, becomes an obvious potential strategy for this psychiatric disease [34].

Ketamine has been in the clinic as an analgesic anaesthetic since the 1960s [233], and now some 40 years later memantine has been approved for the symptomatological treatment of Alzheimer’s dementia. Dextromethorphan, which is metabolized to the more potent NMDA antagonist dextrorphan, has been used as a cough suppressant, but whether NMDA antagonism plays a part in this clinical use is not known.

Newer and more potent channel blocking NMDA antagonists, for example, gavestinel [238] and aptigenel (Cerestat) [239], have entered stroke trials, but the clinical outcome has not been encouraging and the trials have been abandoned. Despite the site of action within the channel, there have been reports of selectivity toward GLU_{N2C} subunit-containing receptors for memantine (see [237]) and for dextromethorphan [240] and of slower kinetics for MK-801 at GLU_{N2C} -containing receptors [240].

Noncompetitive NMDA receptor antagonists: Polyamines such spermine and spermidine (Fig. 10.9) appear to be natural modulators of NMDA receptor function [38]. In addition to the potentiating effects (see above), they also produce a glycine-independent NMDA antagonism, probably via several sites [241, 242]. To some extent their action is mimicked by zinc, which displays a high-affinity voltage-independent inhibition, except that this cation shows strong selectivity for the GLU_{N2A} subunits over GLU_{N2B} with less potency at the other GLUN subtypes [243].

Ifenprodil (Fig. 10.10), a phenylethanolamine, is a potent noncompetitive NMDA antagonist [244], also glycine independent but with a strong preference for GLU_{N2B} -containing receptors over GLU_{N2A} and again with little or no activity at GLU_{N2C} / GLU_{N2D} [245, 246]. Unfortunately, the utility of ifenprodil is limited by its action, at sigma receptors [247] and at voltage-dependent calcium channels [248] as is that of the close analog eliprodil (Fig. 10.10) [249]. Other analogs, for example, Ro25-6981 (Fig. 10.10) [250] and CP101,606 (Fig. 10.10) [251], show similar selectivity for GLU_{N2B} but with reduced sigma and calcium channel properties. Some of these compounds have adverse effects on cardiac excitability and/or are metabolized rapidly by the liver.

It is hoped that later compounds such as benzamides [252], benzimidazoles [253], and isoquinolin-pyrimidines [254] are free of these and other disadvantages. These GLU_{N2B} -selective compounds, which act at the N-terminal domain, appear to have the beneficial properties of anticonvulsant, neuroprotective, analgesic, and so on, without the psychotomimetic downside and may even enhance some forms of memory [221, 255, 256]. This may be viewed as somewhat surprising since this subunit is widely expressed in the forebrain including the hippocampus [39, 45] and the GLU_{N2B} subunits appear to be involved in synaptic plasticity [257, 258]. On the other hand, there may be a predominance of the GLU_{N2B} subunit in extrasynaptic NMDA receptors [259, 260], for example, those activated by spillover as may occur in seizure activity, by high extracellular levels of glutamate as in ischemia, or high-frequency inputs as may occur in some pain states. Indeed, such extrasynaptic NMDA receptors appear to play a crucial role in some forms of neuronal cell death [261]. If GLU_{N2B} -containing receptors are less involved in normal synaptic processing of sensory information, then antagonists selective for these subunits may be expected to have less perceptual disturbances than nonselective compounds.

10.3.3 AMPA Receptor Allosteric Potentiators

Pyrrolidinones and benzamides: Several classes of positive allosteric modulators of AMPA receptor have been identified which have no effect on AMPA receptor function alone but in the presence of agonist binding can markedly enhance ion flux through the channel. The effects of several modulators from distinct chemical classes on the magnitude of the inward current evoked by application of AMPA are presented in Figure 10.11. Note the marked differences in the potency and efficacy of these compounds. One of the first modulators to be described was the pyrrolidinone 1-(4-methoxybenzoyl)-2-pyrrolidinone (aniracetam), which was shown to selectively potentiate quisqualate- and AMPA-evoked currents (but not kainite- or NMDA-evoked responses) in *Xenopus* oocytes as well facilitate glutamatergic synaptic transmission in electrophysiological recordings from hippocampal slices (Fig. 10.11) [262]. A structurally related series of benzamide compounds, also known as “AMPAkines,” including 1-(quinoxalin-6-ylcarbonyl)-piperidine (CX516), 1-(1,4-benzodioxan-6-ylcarbonyl)piperidine (CX546), and 2*H*,3*H*,6*aH*-pyrrolidino (2'',1''-3',2')1,3-oxazino(6',5'-5,4)benzo[*e*]1,4-dioxan-10-one (CX614), have been identified that also selectively enhance AMPA receptor-mediated synaptic responses in vitro and in vivo [263–269].

Benzothiadiazides: A structurally distinct series of benzothiadiazide modulators were identified following the observation that 7-chloro-3-methyl-2*H*-1,2,

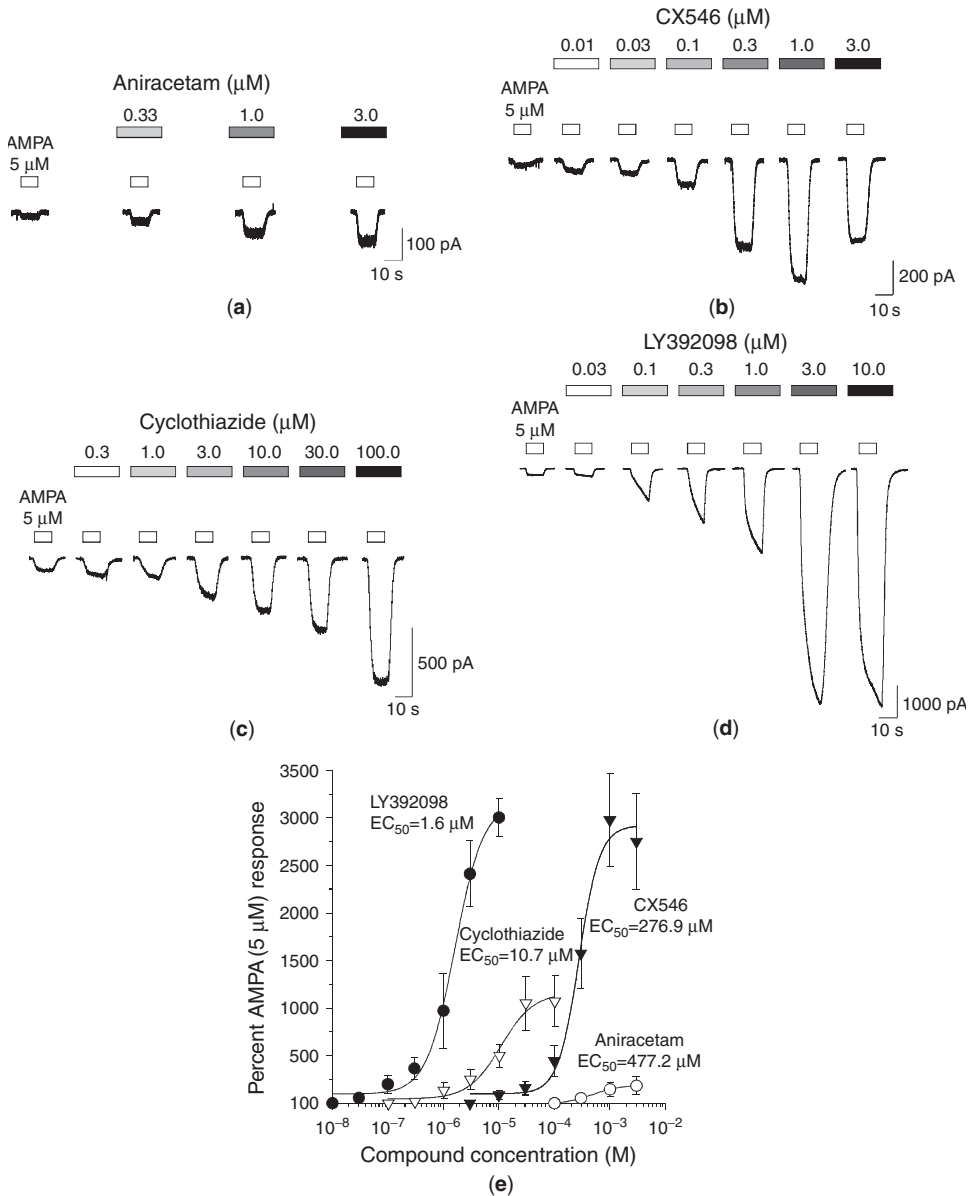

Figure 10.11 Concentration–response profile for aniracetam, cyclothiazide, CX546, and LY392098. Concentration–response profile for (a) aniracetam (0.3–3.0 mM, $n = 5$), (b) CX546 (0.01–3.0 mM, $n = 7$), (c) cyclothiazide (0.3–100 μM, $n = 9$), and (d) LY392098 (0.03–10.0 μM, $n = 8$) potentiation was assessed by measuring the responses of acutely isolated rat cortical neurons to 5 μM AMPA alone and in the presence of potentiator. Responses to each compound were from different neurons and reflect excerpts from a continuous chart recording. Each concentration of the potentiators was applied for approximately 20 s prior to application of AMPA. All compounds enhanced AMPA responses in concentration-dependent manner in the absence of any effects on their own. (e) Plot of average degree of potentiation as percent of response to AMPA (5 μM) alone for each concentration of each compound tested. Points represent mean \pm standard deviation (SD).

Figure 10.12 AMPA receptor allosteric potentiators.

4-benzothiadiazine 1,1-dioxide (diazoxide) selectively augmented quisqualate currents and enhanced excitatory postsynaptic currents in recordings from cultured hippocampal neurons [270]. Subsequent studies with a structurally related compound, 6-chloro-3,4-dihydro-3-(5-norbornen-2-yl)-2*H*-1,2,4-benzothiadiazine-7-sulfonamide-1,1-dioxide (cyclothiazide), demonstrated that AMPA receptor potentiation was associated with long bursts of glutamate-induced channel openings [271]. Other compounds from this class of modulators include 7-chloro-3-methyl-3,4-dihydro-2*H*-1,2,4-benzothiadiazine 1,1-dioxide (IDRA-21) and (4-[2-(phenylsulfonylamino)ethylthio]-2,6-difluorophenoxyacetamide (PEPA) [272, 273].

Biarylpropylsulfonamides: More recently, a series of biarylpropylsulfonamides have been reported, including (*R,S*)-*N*-2-(4-(3-thienyl)phenyl)propyl-2-propanesulfonamide (LY392098), *N*-2-[4-(4-cyanophenyl)phenyl]propyl 2-propanesulfonamide (LY404187), *N*-2-(4-(*N*-benzamido)phenyl) propyl-2-propanesulfonamide (LY395153), and (*R*)-4'-[1-fluoro-1-methyl-2-(propane-2-sulfonylamino)-ethyl]-biphenyl-4-carboxylic acid methylamide (LY503430) [274–278]. Similar to the functional consequences reported for other classes of positive allosteric modulators, the biarylpropylsulfonamides selectively enhance ion flux in recombinant homomeric receptors and native heteromeric receptors and potentiate AMPA receptor-dependent synaptic responses in brain slices and in vivo [274, 279–281].

Apart from their structural differences, positive allosteric modulators can display marked preferences for modulating the flip-and-flop alternative splice variants of AMPA receptors. Cyclothiazide, LY404187, and LY503430 preferentially modulate homomeric receptors composed of the flip isoform of GLU_{A1–4} subunits [62, 278, 282]; whereas aniracetam and PEPA display greater activity at receptors expressing flop splice-variants [273, 282]. Site-directed mutagenic studies have indicated that splice-variant selectivity depends in large part on the identity of a single amino acid within the flip/flop extracellular domain. The presence of a serine or an asparagine residue at the position corresponding to 775 in full-length human GLU_{A2} subunit is critical for determining sensitivity of cyclothiazide or LY404187 to flip or flop isoforms, respectively [281, 282]. Similarly, the preferential flop receptor sensitivity to aniracetam is dependent on this residue [282].

Positive allosteric modulators of AMPA receptors also can have distinct biophysical mechanisms of action by preferentially affecting deactivation or desensitization of the receptor. For example, cyclothiazide and PEPA attenuate desensitization with minimal effects on deactivation, whereas, aniracetam slows deactivation with less effect on desensitization [273, 282]. Other molecules such as CX614 can affect both processes [267, 283]. Insights into the molecular determinants for modulation of deactivation and desensitization of AMPA receptors have come from studies of cocrystal structures of the GLU_{A2} LBC in complex with cyclothiazide (desensitization) or aniracetam and CX614 (deactivation) [64, 283]. For cyclothiazide, two molecules bind in the dimer interface between adjacent LBCs such that the long axis of each compound spans the interface between the upper and lower domains of the LBC. In so doing, cyclothiazide stabilizes the dimer interface, precluding rearrangement of the dimer and subsequent desensitization [64]. For aniracetam and CX614, only one molecule binds at the dimer interface and the long axes of the molecules are oriented approximately parallel to the interface. These modulators do not markedly infiltrate the interface between the upper and lower domains of the LBC but rather bind adjacent to the “hinge” of the clamshell LBC. These molecules exert their

actions by stabilizing the closed-cleft, glutamate-bound conformation of the LBC and thereby attenuate unbinding of glutamate and deactivation of the receptor [283]. It should be noted that although modulators can preferentially affect one biophysical process over another, they are not completely selective (e.g., aniracetam has some effect on desensitization). The lack of exclusivity in modulation of deactivation and desensitization most likely results from the fact that some overlap exists in the binding sites of the modulators [283].

An accumulating body of evidence suggests that positive allosteric modulation of AMPA receptors may have therapeutic implications in a variety of neurological and psychiatric disorders. Early clinical studies with the pyrrolidinone compounds piracetam and aniracetam showed modest results in treating cognitive deficits associated with several neurological diseases, including Parkinson's disease, Alzheimer's disease, and schizophrenia [284–286], prompting their informal classification as “nootropic agents” (i.e., compounds that facilitate learning and memory). As described above, AMPA receptor modulators enhance glutamatergic synaptic activity due to the direct potentiation of AMPA receptor function. In addition, these compounds can indirectly recruit voltage-dependent calcium channels and NMDA receptor activity [279]. Enhanced calcium influx through NMDA receptors is known to be a critical step in initiating long-term modifications in synaptic function (e.g., LTP). These modifications in synaptic function may be substrates for certain forms of memory encoding [269]. Consistent with a recruitment of NMDA receptor activity, AMPA receptor modulators have been shown to facilitate the induction of LTP as well as improve performance in animal models of cognitive function requiring different mnemonic processes [263, 264, 287–290]. Along with their nootropic actions, these positive AMPA receptor modulators have been shown to be active in other models of disease. For example, piracetam is efficacious in several models of anxiety, including the social interaction test, elevated plus maze, and Vogel's conflict test [291, 292]. CX516 (and structural analogs) has been demonstrated to suppress hyperactivity in animal models of attention-deficit hyperactivity disorder (ADHD) and positive symptoms of schizophrenia [293, 294].

In addition to enhancing glutamatergic synaptic transmission, AMPA receptor modulators have been shown to increase levels of the neurotrophin brain-derived neurotrophic factor (BDNF) in neuronal culture [295, 296] and in vivo [278, 297]. Increases in BDNF levels have been associated with the activity of several classes of antidepressant therapies and with development, growth, and maintenance of neurons, which may be a critical component of antidepressant efficacy [298]. BDNF mRNA has been shown to be downregulated in rats tested in animal models of behavioral despair, including restraint stress and the forced-swim test, and this reduced expression can be reversed by antidepressant treatment [299, 300]. Because of their ability to enhance BDNF expression, allosteric modulation of AMPA receptors has been proposed as a novel strategy for the treatment of depression [301]. Indeed, administration of the biarylpropylsulfonamide LY392098 reduced immobility in both mice and rat forced-swim tests, a model of behavioral despair that can be used to detect antidepressant compounds [302]. In addition, the effects of LY392098 could be blocked by the selective AMPA receptor antagonist LY300168, indicating that the effect of the potentiator was mediated through AMPA receptors [302]. Finally, the neurotrophic effects of AMPA receptor potentiators have been extended experimentally to models of Parkinson's disease. In these studies, administration of

LY503430 was shown to reverse the neurochemical and behavioral deficits associated with dopamine-depleting brain lesions as well as produce modest enhancements in BDNF expression in the dopamine cell body region of the substantia nigra [303]. While the precise mechanisms through which positive allosteric modulators of AMPA receptors exert their beneficial effects in models of antidepressant activity and Parkinson's disease remain to be elucidated, these results suggest that positive modulators may be efficacious in a wide range of therapeutic targets.

10.3.4 AMPA Receptor Allosteric Antagonists

2,3-Benzodiazepines: The first examples of negative allosteric modulators of AMPA receptors came from a series of 2,3-benzodiazepines typified by 1-(4-aminophenyl)-4-methyl-7,8-methylenedioxy-5*H*-2,3-benzodiazepine (GYKI 52466) and 1-(4-aminophenyl)-4-methyl-7,8-methylenedioxy-4,5-dihydro-3-methylcarbamoyl-2,3-benzodiazepine (GYKI 53784) (also known as LY303070; racemate LY300168) (Fig. 10.13) [304, 305]. In contrast to the 1,4-benzodiazepines, the 2,3-benzodiazepines have no affinity for the GABA_A receptor but block native and recombinant AMPA receptors with low-micromolar potency in a noncompetitive manner [175, 306–309]. In addition, these compounds have very weak potency at kainate receptors and as such have become an important tool for distinguishing between AMPA and kainate receptor-mediated responses.

Quinazolinones: Another class of selective negative allosteric modulators of AMPA receptors from a quinazolinone series has been reported and includes 3-(2-chlorophenyl)-2-[2-(6-diethylaminomethyl-pyridin-2-yl)-vinyl]-6-fluoro-3*H*-quinazolin-4-one (CP-465,022) and 2-{2-[3-(2-chloro-phenyl)-6-fluoro-4-oxo-3,4-dihydro-quinazolin-2-yl]-vinyl}-nicotino nitrile (CP-526,427) [310–313].

Although crystallographic analyses of the AMPA receptor LBC in conjunction with negative allosteric modulators have not been performed, pharmacological and receptor binding experiments have ruled out some possible binding sites. For example, [³H]CP-526,427 specific binding to rat forebrain membranes was not significantly affected by the orthosteric agonists glutamate, AMPA, and kainate or the orthosteric antagonist YM-90K, confirming the noncompetitive nature of CP-526,427 [311]. However, [³H]CP-526,427 binding was inhibited by the noncompetitive 2,3-benzodiazepine antagonist GYKI52466, suggesting overlap in the binding sites of these negative allosteric modulators. Similar to the results with orthosteric compounds, the positive allosteric modulators cyclothiazide, 1-BCP, or CX-516 at concentrations that

Figure 10.13 AMPA receptor allosteric antagonists.

are known to enhance AMPA receptor-mediated currents were ineffective in blocking [^3H]CP-526,427 specific binding [311]. Consistent with these latter data, studies have shown that while mutation of the serine 775 residue in the flip/flop domain to glutamine (corresponding residue in kainate receptors) eliminates the activity of cyclothiazide, this substitution has no effect on the antagonism of the 2,3-benzodiazepine GYKI53655 [314]. Both of these observations suggest that the binding sites of negative and positive allosteric modulators of AMPA receptors are distinct.

The possibility that negative allosteric modulators of AMPA receptors may provide a novel anticonvulsant therapy has been explored extensively in recent years. Several of the 2,3-benzodiazepines [e.g., GYKI52466, LY300164 (Talampanel)] have potent anticonvulsant activity in a broad range of in vivo epilepsy models (for review, see [315]). In addition, LY300164 can potentiate the anticonvulsant action of known antiepileptic medications, including valproate, carbamazepine, and phenobarbital [316]. A potential limitation of negative allosteric modulators as suggested by the effects of competitive antagonists is a narrow therapeutic window due to adverse or undesirable side effects. For example, NBQX blockade of AMPA receptors is known to produce ataxia and can impair learning and memory in rats [317]. In contrast, GYKI52466 does not block the induction of LTP in hippocampal brain slices [318] and LY300164 does not exacerbate the ataxia and cognitive impairment of traditional antiepileptics [316]. More importantly, in a recent clinical trial, LY300164 significantly reduced seizure frequency in patients with partial refractory seizures in the absence of cognitive impairment (although ataxia was observed in 26% of the subjects) [319]. While no pivotal clinical trials have been completed, these results are encouraging and suggest that negative allosteric modulators may be efficacious as anticonvulsants. Finally, evidence suggests that several other diseases associated with elevated brain glutamate concentrations also may benefit from AMPA receptor negative modulators, particularly because of their ability to block glutamatergic neurotransmission without having to surmount the high levels of endogenous glutamate. Negative modulators have been shown to be beneficial in studies using animal models of ischemia stroke, Parkinson's disease, multiple sclerosis, and persistent pain (for review, see [315]).

10.3.5 Kainate Receptor Allosteric Potentiators

Concanavalin A: As previously discussed, kainate receptors exhibit rapid desensitization upon continued agonist application. Therefore many studies of kainate receptors, especially those involving transfected stable cell lines, use concanavalin A, a lectin from jack bean, to block agonist desensitization. The exact method of action of concanavalin A remains to be elucidated. However, it is known that concanavalin A binds to several glycosylation sites on the extracellular domain of the receptor [320]. Concanavalin A has been reported to increase agonist affinity at kainate receptors. Paternain et al. [321] reported that the EC_{50} for kainate at rat $\text{GLU}_{\text{K}6}$ following treatment with concanavalin A was 25-fold lower than the value from untreated receptors. Jones et al. [322] reported that the EC_{50} for SYM2081 at rat $\text{GLU}_{\text{K}6}$ was also reduced by concanavalin A treatment. However, other studies have demonstrated only a small effect or no effect on agonist EC_{50} values at kainate receptors comprised of $\text{GLU}_{\text{K}5}$ [179, 323]. $\text{GLU}_{\text{K}7}$ receptors are insensitive to concanavalin A, a feature which has limited their study.

10.3.6 Kainate Receptor Allosteric Antagonists

NS3763: Recently, the first allosteric antagonists of kainate receptors have been described. 5-Carboxyl-2,4-di-benzoamido-benzoic acid (NS3763) was shown to inhibit glutamate- or domoate-evoked currents in HEK293 cells recombinantly expressing human kainate receptors (Fig. 10.14) [160]. NS3763 was found to insurmountably antagonize both domoate and glutamate. The noncompetitive nature of NS3763 was further evidenced by its inability to inhibit [^3H]ATPA binding to $\text{GLU}_{\text{K}5}$ receptors. NS3763 was found to be selective for the $\text{GLU}_{\text{K}5}$ receptor subtype ($\text{IC}_{50} = 1.6 \mu\text{M}$) versus $\text{GLU}_{\text{K}6}$, AMPA, or NMDA receptors ($\text{IC}_{50} > 30 \mu\text{M}$). Perhaps the most interesting property of NS3763 is that, unlike other $\text{GLU}_{\text{K}5}$ -selective antagonists such as the decahydroisoquinolines or willardiine derivatives (see above), it has been reported to be selective for homomeric $\text{GLU}_{\text{K}5}$ versus heteromeric $\text{GLU}_{\text{K}2}/\text{GLU}_{\text{K}5}$ or $\text{GLU}_{\text{K}5}/\text{GLU}_{\text{K}6}$ receptors, making this compound a potentially useful tool for examining the subunit composition of native kainate receptors [183a].

2-Arylureidobenzoic acids: A series of 2-arylureidobenzoic acids have also been described as noncompetitive $\text{GLU}_{\text{K}5}$ -selective antagonists [324, 325]. Like NS3763, these compounds are potent antagonists at $\text{GLU}_{\text{K}5}$ channels. 4-Chloro-2-(3-naphthalen-2-yl-ureido)-benzoic acid (2-arylureidobenzoic acid) and 2-[3-(3-bromophenyl)ureido]-4-chlorobenzenesulfonic acid are the most potent compounds from this series described to date, blocking calcium influx evoked by $2 \mu\text{M}$ domoate at recombinant human $\text{GLU}_{\text{K}5}$ with IC_{50} values of 1.2 and $1.5 \mu\text{M}$, respectively [325]. These compounds are selective for $\text{GLU}_{\text{K}5}$ versus $\text{GLU}_{\text{K}6}$, blocking domoate ($0.2 \mu\text{M}$)-evoked calcium influx at recombinant human $\text{GLU}_{\text{K}6}$ receptors with reported IC_{50} values of $62 \mu\text{M}$ for 2-arylureidobenzoic acid and $37 \mu\text{M}$ for 2-[3-(3-bromophenyl)ureido]-4-chlorobenzenesulfonic acid. Neither compound showed significant activity at AMPA receptors, with $\text{IC}_{50} > 100 \mu\text{M}$ for blocking glutamate ($25 \mu\text{M}$)-evoked calcium influx at recombinant human $\text{GLU}_{\text{A}1-4}$ [325]. Like NS3763, these compounds do not inhibit the binding of [^3H]ATPA to recombinant human $\text{GLU}_{\text{K}5}$ receptors.

10.4 FUTURE PERSPECTIVES

The cloning and expression of recombinant proteins for NMDA, AMPA and kainate receptors have facilitated the identification of many potent and selective compounds. The use of these agents as pharmacological tools both in vitro and in vivo has enabled recent advances in our understanding of the role of ionotropic glutamate receptors in the central nervous system. More recently, agents have been discovered which show increased potency and improved selectivity for subtypes within each of the three classes of receptor. X-ray crystallographic data for each receptor have

Figure 10.14 KA receptor allosteric antagonists.

allowed an insight into the topographical structure of the ion channel and the potential binding interactions of ligands to specific domains. As new agents emerge that show high-affinity interactions with either orthosteric or allosteric sites, we may expect to increase our knowledge of chemical features that either enhance affinity or confer greater selectivity. A key area of future research will be to better understand the specific subunit composition that comprises a native ion channel receptor. Additionally, it will be important to explore the influence of such heterogeneity on the behavior of pharmacological agents. The critical role of ionotropic glutamate receptors in synaptic transmission makes them ideal targets for therapeutic intervention. An emergent area of research is work on how glutamate receptors are altered in disease (e.g., distribution, phosphorylation state, subunit composition). It may be necessary for us to be able to model such changes in order to be successful in specific pharmacological intervention.

11.1 BACKGROUND/RECEPTOR CLASSIFICATION

Metabotropic glutamate (mGlu) receptors are a relatively novel heterogenous family of G-protein-coupled receptor proteins which function to modulate glutamate transmission via presynaptic, postsynaptic, and glial mechanisms. Currently, eight subtypes of mGlu receptors (mGlu1–8) have been cloned, and their structure and function have been described in various earlier reviews [1–6]. Briefly, group I mGlu receptors are positively coupled to phospholipase C and include mGlu1 and mGlu5

(and their splice variants). Both group II mGlu receptors (mGlu2 and mGlu3) and group III (mGlu4, mGlu6, mGlu7, and mGlu8) are coupled via G_i to inhibition of adenylate cyclase. mGlu receptors have been divided into these three groups based on (1) structural homology of about 70% within groups and about 40% between groups, (2) similar transduction mechanisms or G-protein coupling, and (3) shared pharmacological properties within a group [7, 8]. Each receptor subtype and in some cases alternatively spliced versions are uniquely distributed, though many synapses likely express multiple subtypes, suggesting some redundancy of function (see Fig. 11.1).

Due to the high structural homology within mGlu groups, many current agents, particularly orthosteric (or glutamate binding site) agonist and antagonist ligands, are selective for mGlu receptor groups (group I, II, and III) but they do not distinguish subtypes within a group (e.g., mGlu2 and mGlu3). The discovery of agents with subtype selectivity within an mGlu receptor group has now greatly progressed with the advent of library screening for functional antagonists and potentiators which generally act by an allosteric mechanism (9–11).

The literature on the effects of many known pharmacological agents across all eight mGlu receptor subtypes has been previously reviewed [1, 2, 8]. In this chapter, we review the pharmacology of both orthosteric and allosteric targets for mGlu receptors and briefly comment on their usefulness as pharmacological tools to drive new knowledge in this area.

Figure 11.1 Glutamate synapse. (See color insert.)

11.2 ORTHOSTERIC PHARMACOLOGICAL AGENTS

11.2.1 Group I Selective Orthosteric Agonists

Quisqualate: Before the cloning of mGlu receptor subtypes in the early 1990s, mGlu receptors were generally characterized by the ability of glutamatergic acidic amino acid analogs to activate the phosphoinositide hydrolysis second-messenger system or subsequently increase intracellular calcium mobilization in a number of preparations, including cultured neurons, brain slices, cultured glia, and *Xenopus* oocytes injected with rat brain messenger ribonucleic acid (mRNA). The pharmacology of this response was clearly distinguished from known ionotropic glutamate receptor subtypes at that time [12, 13]. Quisqualate (Fig. 11.2) was the most potent mGlu receptor agonist in eliciting these metabotropic responses, with submicromolar potency in many tissues. Quisqualate also has high potency as an α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor agonist, and this has generally precluded the use of quisqualate to study mGlu receptors in most preparations. Nevertheless, quisqualate has been useful as a group I selective agonist in recombinant systems and rat brain tissues. In particular, ^3H -quisqualate was used as a high-affinity ligand to study structure/function of cloned mGlu receptors in a recombinant system where its AMPA receptor activity would not interfere [14].

1*S*,3*R*-ACPD: The conformationally constrained cyclopentane derivative of glutamate, 1-amino-cyclopentane-1,3-dicarboxylic acid (ACPD), gives rise to four different isomers; 1*S*,3*R*, 1*R*,3*S*, 1*S*,3*S*, and 1*R*,3*R* [12]. Racemic (\pm)*trans*-ACPD [or *cis*-ACPD according to International Union of Pure and Applied Chemistry (IUPAC) nomenclature] was the first mGlu receptor selective agonist, shown to activate phosphoinositide hydrolysis in rat hippocampus at concentrations having no effects on ionotropic glutamate receptor ligand binding [15, 16]. Separation of (+)*trans*-ACPD into its 1*S*,3*R* and 1*R*,3*S* isomers demonstrated that 1*S*,3*R*-ACPD (Fig. 11.2) was the active component responsible for stimulation of phosphoinositide hydrolysis in rat brain tissue [17]. Also, consistent with its metabotropic glutamate receptor activity in rat brain slices, 1*S*,3*R*-ACPD (not 1*R*,3*S*-ACPD) was found to stimulate intracellular calcium mobilization in neurons [18]. However, 1*S*,3*R*-ACPD also acts as an agonist at multiple mGlu receptor subtypes, including mGlu1, mGlu2, mGlu3, mGlu4, mGlu5, mGlu6, and mGlu8 (see [8]). This non-subtype selective mGlu receptor agonist profile likely explains why a range of pharmacological actions have been reported for 1*S*,3*R*-ACPD (see [1, 3, 13]).

3,5-DHPG: (*R,S*)-3,5-Dihydroxyphenylglycine (3,5-DHPG; Fig. 11.2) was described as a more potent activator of rat mGlu1a receptors expressed in *Xenopus*

Figure 11.2 Group I selective orthosteric agonists.

oocytes than (\pm)*trans*-ACPD [19], when (\pm)*trans*-ACPD was one of the few known selective mGlu receptor agonists. In rat hippocampal CA3 pyramidal cells 3,5-DHPG, like ACPD, produced a slow excitation resulting from depression of inhibitory currents (I_{AHP} and I_{M}) [19]. This showed phenylglycines such as 3,5-DHPG could mimic the actions of more “glutamate-like” diacidic amino acids at mGlu receptors and led to the synthesis of many additional phenylglycines in the search to find more selective orthosteric agonists and antagonists [8, 20].

Subsequently, second-messenger studies in the rat hippocampus reported that 3,5-DHPG activated phosphoinositide hydrolysis but, unlike 1*S*,3*R*-ACPD, had no effect on forskolin-stimulated cAMP formation [21]. The activity of 3,5-DHPG on the phosphoinositide hydrolysis pathway in the rat hippocampus resided in the *S* isomer [22]. 3,5-DHPG exhibits about equal agonist potencies at mGlu1 and mGlu5 receptor subtypes but has no agonist or antagonist activities at recombinant rat and/or human group II (mGlu2 and mGlu3) or group III (mGlu4, 6, 7, or 8) mGlu receptors (see [23–26]).

The group I (mGlu1/5) selectivity of 3,5-DHPG has made this compound the most widely used for investigating the role of group I mGlu receptors in native tissues. In hippocampus and striatum 3,5-DHPG, although not directly exciting neurons, enhanced neuronal excitations by the potentiation of the ionotropic glutamate receptor agent *N*-methyl-D-aspartate (NMDA) [27, 28]. Central administration of 3,5-DHPG has been shown to lead to the induction of seizures and/or neurotoxicity [29–31] and produced pain-like states when administered centrally [32, 33] or peripherally [34] in animals. Studies such as these are consistent with the potential anticonvulsant, neuroprotectant, and analgesic actions of selective group I receptor antagonists in animals [35–37].

CHPG: (*R,S*)-2-Chloro-5-hydroxyphenylglycine (CHPG) is a *chloro*-substituted phenylglycine analog of 3HPG (see Fig. 11.2). CHPG has significant mGlu5 receptor activity (median effective concentration EC_{50} 750 μM) but no appreciable mGlu1 receptor activity at up to 10,000 μM [38], making it potentially useful for examining the relative role of mGlu5 versus mGlu1 receptors. Nevertheless, the low potency of CHPG and the more recent discovery of highly potent and selective mGlu5 receptor antagonists limit its usefulness to study mGlu5 receptor activation.

11.2.2 Group I Selective Orthosteric Antagonists

Before the 1990s the only selective antagonist for mGlu receptor responses, in this case phosphoinositide hydrolysis in rat brain tissues, was L-2-amino-3-phosphonopropanoate (L-AP3) (see [8, 12]). The search for more potent competitive mGlu receptor antagonists led to the recognition that various other phenylglycine derivatives possess antagonist, agonist, and even mixed agonist–antagonist activities across multiple subtypes of mGlu receptors (see [8, 39, 40]). In addition to certain recombinant receptors, many of these compounds were characterized in the neonatal spinal cord preparation [41, 42] where group I agonists (e.g., 1*S*,3*R*-ACPD, 3,5-DHPG) depolarize motoneurons, while group II selective agonists (e.g., 1*S*,3*S*-ACPD) and group III selective agonists (e.g., L-AP4) depress the monosynaptic component of the dorsal root-evoked ventral root potential (mDR-VRP).

(*S*)-4CPG: Substitution of the *para*-hydroxy group in 3,5-dihydroxyphenylglycine with a carboxy group, as in *S*-4-carboxy phenylglycine (*S*-4CPG; Fig. 11.3),

Figure 11.3 Group I selective orthosteric antagonists.

produced a mGlu1 selective competitive group I antagonist (median inhibitory concentration IC_{50} 10–100 μ M) with weak agonist activity at mGlu2 (EC_{50} \sim 500 μ M) but no activity at mGlu4 receptors [8, 43, 44].

(S)-MCPG: The incorporation of an α -methyl group into *S*-4CPG, as in *S*- α -methyl-4-carboxyphenylglycine [(*S*)-MCPG; Fig. 11.3] produced group I antagonist potency with about equivalent antagonist potency at mGlu2 receptors [8, 43–45], and no appreciable mGlu4 receptor activity. (*S*)-MCPG also had significant antagonist activity at mGlu8 receptors [26, 46, 47]. (*S*)-MCPG blocks the actions of L-AP4 in the neonatal spinal cord [47], suggesting that mGlu8 receptors mediate the depressant effects of L-AP4 in that preparation. (*S*)-MCPG became a very widely used pharmacological tool for probing the functions of mGlu receptors in cellular processes (see [40]). However, the discovery of more potent, selective, and systemically available non-phenylglycine antagonist compounds limits the current usefulness of (*S*)-MCPG.

(S)-4C3HPG: (*S*)-4C3HPG (Fig. 11.3) is an antagonist at mGlu1 receptors but is about equipotent as an agonist at mGlu2, with no appreciable activities at mGlu4 [43, 44]. Both group I antagonists and group II agonists have been shown to be anticonvulsant in certain animal models of epilepsy, and (*S*)-4C3HPG combines both of these activities in one molecule. Interestingly, Thomsen et al. [48] found that (*S*)-4C3HPG was active following intracerebral injection as an anticonvulsant against audiogenic seizures in DBA/2 mice. Thus, compounds with a group II agonist/group I antagonist profile might be more effective than either mGlu activity alone. This may also be the case for ischemia, as (*S*)-4C3HPG reduces infarct size following focal ischemia in rats [49], where group II mGlu2/3 receptor agonists per se are not active in rat stroke models [50].

AIDA: (*R,S*)-1-aminoindan-1,5-dicarboxylic acid (AIDA; Fig. 11.3) is a reported selective antagonist of mGlu1 (pA_2 = 4.21), with weaker antagonist action at mGlu5, but was inactive at mGlu2 receptors [51]. The discovery of more potent and selective mGlu1 antagonists has limited the use of this compound. Nevertheless, target validation studies using centrally administered AIDA are consistent with other literature suggesting use of mGlu1 antagonists as analgesics [52], anxiolytics [53], and neuroprotectants [54, 55].

LY367385: ((+)-2-Methyl-4-carboxyphenylglycine (LY367385) is a micromolar potent and subtype selective competitive mGlu1 receptor antagonist [8, 56, 57].

LY367385 is not systemically active, but its relatively high water solubility and low micromolar potency have made it useful to explore mGlu1 receptor functions.

For example, the intracerebral injection of either LY367385 or AIDA was shown to be anticonvulsant in three different rodent models, including DBA/2 mice, lethargic mice, and genetically epilepsy prone rats [58]. This suggests a role for mGlu1 antagonists in the treatment of epilepsy. Likewise, LY367385 selectively reduced noxious excitatory responses in the rat thalamus [59], also suggesting a role for mGlu1 receptors in nociceptive processes of the brain. LY367385 is neuroprotectant in various models, including NMDA-induced excitotoxicity in vitro and in vivo, and intraventricular administration reduced hippocampal cell death in gerbils following transient global ischemia [57, 60].

11.2.3 Group II Selective Orthosteric Agonists

L-CCG-I: 2-(Carboxycyclopropyl)glycines (CCGs) are conformationally restricted glutamate analogs in which the proximal and distal carboxy groups can exist in either an extended or folded conformation. Studies with the isomers of CCG suggested that the extended conformation is preferred for mGlu receptor agonist potency and selectivity. In particular, L-CCG-I (Fig. 11.4) effectively activates multiple mGlu receptor subtypes, while having no effects on ionotropic glutamate receptors [8, 61–65]. As there are now compounds with much greater subgroup or subtype selectivity than L-CCG-I (see below), the usefulness of L-CCG-I as a pharmacological tool is fairly limited.

DCG-IV: Combining elements that led to the mGlu selective agonist L-CCG-I (extended glutamate conformation) and the potent NMDA agonist L-CCG-IV (folded glutamate conformation) resulted in the 2',3'-dicarboxycyclopropylglycine analog DCG-IV (Fig. 11.4) [63]. DCG-IV was described as a highly potent (nanomolar) and relatively selective agonist for group II mGlu receptors [64, 66]. However, at higher micromolar concentrations it is an antagonist at group I and group III mGlu receptor subtypes [64] and has been reported to activate NMDA receptors in native tissues [67–69]. ³H-DCG-IV has shown to bind to CHO cell membranes expressing recombinant rat mGlu2 receptors with relatively high affinity

Figure 11.4 Group II selective orthosteric agonists.

($K_d = 160$ nM) [70]. In rat brain cortex homogenates, ^3H -DCG-IV bound to a single site with $K_d = 180$ nM and $B_{\text{max}} = 780$ fmol/mg protein, and this binding was potently displaced by the group II antagonist LY341495 and group II agonist LY354740 [71]. Thus, ^3H -DCG-IV appears to be a useful ligand for studies of mGlu2 (and likely mGlu3) in native tissues.

MCG-I: Placement of a methoxymethyl substituent on the cyclopropane ring of L-CCG-I (see Fig. 11.4) has led to additional compounds with reported group II mGlu receptor selectivity. These include *cis*- and *trans*-MCG-I (Fig. 11.4), which like other group II mGlu agonists potently suppress monosynaptic excitations in the newborn rat spinal cord and/or forskolin-stimulated cAMP formation in cultured rat cortical neurons, with the *trans*-MCG-I isomer being more potent [72–74].

LY446433: The compound C3'-C2'-carboxycyclopropyl glycine was designed as a ring-opened version of LY354740 (Fig. 11.4) [75]. LY446433 was similar in potency and selectivity to LY354740 in vitro (8 and 38 nM EC_{50} at mGlu2 and mGlu3, respectively). When administered orally to rats it was also substantially more potent than LY354740 in the fear-potentiated startle model of anxiety.

LY520303: The compound (2S,1'S,2'R,3'R)-2-(2'-carboxy-3'-hydroxymethylcyclopropyl) glycine (Fig. 11.4) [76] is also a potent (low-nanomolar) agonist for mGlu2 and mGlu3 receptors with no appreciable affinity at ionotropic receptors but less group II mGlu selectivity ($\text{EC}_{50} = 10$ nM and 147 nM at mGlu8 and mGlu6, respectively). The high affinity for mGlu2/3 and 8 makes it unique for studying the contribution of mGlu8 activity along with group II agonist activity. When administered systemically LY520303 was active in anxiety and psychosis models (like mGlu2/3 selective agents) but has not been widely explored in other models to test if addition of mGlu8 activity changes the pharmacological profile or even offers some therapeutic advantage over mGlu2/3 agonists alone. Consistent with its in vitro profile described above, ^3H -LY520303 was shown to bind selectively to cells expressing human mGlu2, 3, or 8 receptors as well as rat forebrain membranes [77].

LY354740: As described above, a number of selective agonists for group II mGlu receptors have now been described. The conformationally restricted bicycloamino acid compound LY354740 ((1S,2S,5R,6S)-2-aminobicyclo[3.1.0]hexane-2,6-dicarboxylate monohydrate) (Fig. 11.4) [78] was the first group II selective agonist which has been shown to have potent pharmacological effects in animals following systemic administration (for a detailed review on this compound see [8]. LY354740 potently activates mGlu2 ($\text{EC}_{50} = 5$ nM) and mGlu3 ($\text{EC}_{50} = 24$ nM) receptors in vitro but has no appreciable effects on other mGlu subtypes or ionotropic glutamate receptors at two to four orders of magnitude higher concentrations [26, 79]. In rat hippocampus, LY354740 suppresses forskolin-stimulated cyclic adenosine monophosphate (cAMP) formation with about the same potency as was observed in mGlu3-expressing cells ($\text{EC}_{50} = 22$ nM), but LY354740 has no effect on phosphoinositide hydrolysis per se [80]. Thus, LY354740 is a highly potent and selective mGlu2/3 agonist at both recombinant human and native rat receptors. In rat brain tissue, ^3H -LY354740 has been shown to bind with high affinity ($K_d = 8$ nM). Specific ^3H -LY354740 in the rat brain exhibited a pharmacology and distribution consistent with the selective labeling of group II mGlu receptors [81]. Consistent with the role of group II mGlu receptors in suppression of glutamate transmission in vitro, systemic LY354740 has been shown to prevent veratridine-evoked glutamate and aspartate release in free-moving rats undergoing microdialysis of the striatum [82]. Orally administered LY354740

potently suppressed fear-potentiated startle responding in rats, indicating it has anxiolytic activity, but unlike other anxiolytics (e.g., diazepam), LY354740 did not produced central nervous system (CNS) depression at any dose [83]. Acute LY354740 administration blocked withdrawal reactions to multiple agents including morphine [84], nicotine [85], and diazepam [86]. However, subchronic administration of LY354740 itself did not produce withdrawal. LY354740 was reported to suppress the in vivo actions of phencyclidine (PCP) in rats [87, 88]. These data suggest that LY354740 may be useful for the treatment of various psychiatric disorders. More recent data in knockout animals have linked the anxiolytic acity of LY354740 (in the elevated plus maze test) to activation of both mGlu2 and mGlu3 [89], while the antipsychotic actions (reversal of PCP behaviors) has been linked to mGlu2 receptors (the role of mGlu3 was not reported) [90]. Using cFos as an index of neuronal activation, Linden et al. [91] found that the anxiolytic actions of LY354740 on the elevated plus maze was associated with stress-induced suppression of *c-fos* induction in the hippocampus. Furthermore, LY354740 per se induces c-Fos within GABAergic brake cells of the lateral portion of the central amygdala, suggesting that the anxiolytic actions of this compound may also be linked to preventing the stress-induced disinhibition of limbic outputs [91, 92].

As has been reported in rats [87], LY354740 attenuated the disruptive effects of an NMDA receptor antagonist on working memory in humans [93]. Also, LY354740 has been reported to reduce anxiety in panic patients that was induced by carbon monoxide [94] and reduced anxiety as measured by the Hamilton-A anxiety scale (HAM-A) in patients with generalized anxiety disorder [95].

Studies have shown that LY354740 was neuroprotective in the gerbil global ischemia model [96] and traumatic neuronal injury in vitro and in vivo [97]. However, LY354740 was not active following permanent focal ischemia in the rat [50]. Thus, the role of group II mGlu receptor agonists as novel neuroprotectants is not yet clear, in particular as it relates to specific therapeutic applications. The use of additional systemically active mGlu2/3 agonists such as LY379268 has also been useful to clarify the potential therapeutic applications for mGlu2/3 receptor agonists (see below).

LY379268/LY389795: The conformationally constrained heterocyclic compounds with either oxygen (LY379268) or sulfur (LY389795) in the 2 position of the bicyclohexane ring have been described as highly potent and systemically active mGlu2/3 agonists (see Fig. 11.4) [98]. In functional assays of human mGlu2- or mGlu3-expressing cells, LY379268 and LY389795 were 3–8 times more potent than LY354740. In a model of limbic seizures in mice induced by 1*S*,3*R*-ACPD [29], as shown previously for LY354740 [78], both LY379268 and LY389795 were anticonvulsant in this test when given parenterally (i.p.) [98]. In another study [88], LY379268 was compared to LY354740 in the PCP model of psychosis in rats. When administered by the subcutaneous (s.c.) route, both compounds blocked motor activations induced by 5 mg/kg PCP; however, LY379268 was about 3 times more potent than LY354740. In monoamine-depleted animals LY379268, similar to the atypical antipsychotic clozapine but unlike haloperidol, reduced PCP behaviors in rats [99]. Carter et al. [100] showed that LY379268 injected into the cortex or thalamus decreased neuronal injury in the retrosplenial cortex induced by the NMDA receptor antagonist MK-801. Therefore, these heterobicyclic compounds, like LY354740, have been useful agents to further validate the therapeutic prospects of

mGlu2/3 agonists following systemic administration in the treatment of psychosis. Likewise, LY379268 has been useful to further study neuroprotection in vivo [101]. Scheifer et al. [102] studied LY379268 in a transgenic mouse model of Huntington's disease. LY379268 increased survival time in these animals. Jones et al. [103] studied both LY379268 and LY389795 for analgesic effects following acute and repeat dosing. Their data suggested that mGlu2/3 receptors may be involved in the mechanisms of hyperalgesia, but tolerance develops rapidly to these effects.

MGS0028: (1*R*,2*S*,5*S*,6*S*)-2-Amino-6-fluoro-4-oxobicyclo[3.1.0]hexane-2,6-dicarboxylic acid (Fig. 11.4) is another nanomolar potent and selective mGlu2/3 receptor agonist that has been shown to have systemic activity in the PCP model of psychosis when given orally to rats [104]. Takamori et al. [105] showed that MGS0028 was also antipsychotic in the conditioned avoidance response assay in rats when given orally. In this study, LY354740 was not active by the oral route in this test. It would appear based on these data that there are differences in mGlu2/3 receptor agonists in these tests that remain unresolved.

*2*R*,4*R*-APDC*: 2*R*,4*R*-4-Aminopyrrolidine-2,4-dicarboxylate (2*R*,4*R*-APDC; LY-314593; see Fig. 11.4) is a conformationally constrained glutamate analog in which a pyrrolidine ring structure is present rather than the cyclopentane group in ACPD [106]. The presence of this nitrogen in the ring produced a group II selective compound with about the same potency as 1*S*,3*S*-ACPD (see [8]). In human mGlu2- or mGlu3-expressing cells 2*R*,4*R*-APDC suppresses forskolin-stimulated cAMP formation with EC₅₀ values of ~400 nM, but there were no appreciable effects on group I (mGlu1 or mGlu5) or group III (mGlu4, mGlu7, mGlu6, or mGlu8) receptors at up to 100 μM [26, 107, 108]. In rat brain slices, 2*R*,4*R*-APDC selectively suppresses forskolin-stimulated cAMP formation at concentrations (1–100 μM) having no effect on phosphoinositide hydrolysis per se [109]. 2*R*,4*R*-APDC, like the other group II selective agonist 1*S*,3*S*-ACPD, was shown to inhibit the development of kindled seizures in rats [110, 111], suggesting a role for group II mGlu receptors in epilepsy. Fisher and Coderre [32] reported that, unlike the group I agonist 3,5-DHPG, 2*R*,4*R*-APDC does not induce spontaneous nociceptive behaviors in rats. These in vivo studies are consistent with the highly selectivity of 2*R*,4*R*-APDC for group II mGlu receptors in vitro or when directly applied in vivo. The potency (micromolar) and selectivity of 2*R*,4*R*-APDC make it a useful in vitro tool. However, the discovery of more potent and systemically acting mGlu2/3 agonists essentially limits the use of this compound to in vitro studies or direct injection into the tissue.

11.2.4 Group II Selective Orthosteric Antagonists

MCCG: (2*S*,1'*S*,2'*S*)-2-Methyl-2-(2'-carboxycyclopropyl)glycine (MCCG; Fig. 11.5) is the α-methyl derivative of the potent group II mGlu receptor agonist L-CCG-I. Pharmacological studies have demonstrated that this simple substitution produces an antagonist for group II mGlu receptors with high micromolar affinity. In the neonatal spinal cord preparation, MCCG blocked the presynaptic depressant effects of 1*S*,3*S*-ACPD and L-CCG-I, while having minimal effects on the depressant effects of L-AP4. MCCG had no effect on the depolarizing response to 1*S*,3*R*-ACPD, indicating no appreciable group I mGlu receptor activity [112]. This group II selective antagonist profile has also been observed in recombinant systems expressing

Figure 11.5 Group II selective orthosteric antagonists.

mGlu1, mGlu2, and mGlu4 cloned receptors [8, 113]. However, in adult rat cerebral cortex slices, MCCG acted as a group/partial agonist, as indicated by suppression of forskolin-stimulated cAMP formation to about 80% of that observed with maximally effective concentration of L-CCG-I [114]. The actions of MCCG on mGlu3 receptors would likely also contribute along with mGlu2 receptors in cAMP response in the rat brain.

LY341495: The α -xanth-9yl-methyl-carboxycyclopropylglycine (LY341495, Fig. 11.5), represented the most potent/optimal substituent from a series of phenylethyl- or diphenylethyl-substituted compounds [115, 116]. Full characterization of LY341495 across human mGlu receptor subtypes indicated that LY341495 is a competitive antagonist with low nanomolar potency at mGlu2 and mGlu3 receptors but at higher concentrations (high nanomolar to micromolar) LY341495 will antagonize mGlu receptor responses in cloned group I and group III receptors [8, 117]. LY341495 had no measurable affinity for ionotropic glutamate receptors. The high potency and selectivity for group II receptors when used at submicromolar concentrations but measurable antagonist actions at other receptors at higher (μ M) concentrations have made LY341495 a highly useful concentration-dependent agent for investigating the potential role of multiple mGlu receptor subtypes. For example, ³H-LY341495 selectively binds to recombinant human and native rat mGlu2 and mGlu3 receptors (K_D values of 1.7 and 0.75 nM, respectively), with a pharmacology (at 1 nM) indicating specific labeling of these receptors in either cells expressing cloned mGlu2/3 subtypes [118] or in the rat brain [119]. This makes ³H-LY341495 a highly useful ligand (under these conditions) for quantitating mGlu2/3 receptor expression, investigating the affinity of other compounds for mGlu2 or mGlu3 binding sites, and investigating the physiological/pathological regulation of these binding sites. Higher concentrations of LY341495 that block all mGlu receptor subtypes ($\sim 100 \mu$ M) have been used to rule out mGlu receptor involvement in physiological processes [120].

LY341495 has also been used *in vivo*, where relatively low parenteral doses (0.3–1 mg/kg) have been shown to block the pharmacological actions of selective group II mGlu receptor agonists. Examples include the elevated plus maze test for anxiety in mice where 0.3 mg/kg *i.p.* LY341495 reversed the anxiolytic actions of LY354740 while having no effect on its own [116] and the PCP model of psychosis in rats where LY341495 (1 mg/kg *s.c.*) alone had no effect on PCP-evoked motor activations, but the inhibitory actions of LY379268 against PCP were completely reversed [88]. These potent and selective actions of LY341495 make it a useful pharmacological agent to study group II mGlu receptor functions. In particular, systemic administration of LY341495 *per se* (0.6–3 mg/kg *i.p.*) has been used to probe how much endogenous

tone exists at mGlu2/3 receptors in vivo in mice. Linden et al. [89] used c-Fos as a marker of neuronal activity and found a widespread pattern of activation suggesting considerable endogenous tone at perisynaptic mGlu2/3 receptors, even under low-stress conditions where synaptic glutamate release/spillover would be expected to be minimal. Xi et al. [121] showed that systemically administered LY341495 increased extracellular glutamate levels, and this was reversed by APDC.

The ability to enhance neuronal activity by blockade of endogenous mGlu2/3 receptors is also supported by additional behavioral and biochemical data. LY341495 administration per se has been shown to be anxiogenic in the mouse elevated plus maze [122], increase locomotor activity in mice [123], stimulate waking and fast electroencephalographic (EEG) power in rats [124], exacerbate behavioral signs and locus ceruleus neuronal firing associated with morphine withdrawal in rats [125], and prevent the ability of *N*-acetylcysteine to inhibit the reinstatement of cocaine seeking in rats [126]. Studies with LY341495 and MGS0039 also suggest that mGlu2/3 receptor antagonists have novel antidepressant-like potential (see below).

MGS0039: (1*R*,2*R*,3*R*,5*R*,6*R*)-2-Amino-3-(3,4-dichlorobenzyloxy)-6-fluorobicyclo [3.1.0] hexane-2,6-dicarboxylic acid (Fig. 11.5), like LY341495, has low nanomolar potency at both mGlu2 and mGlu3 (2.4 and 4.5 nM, respectively) [127]. MGS0039 has very low relative affinities for other mGlu receptors and has been shown to be active when administered systemically to mice and rats. Chaki et al. [128] showed MGS0039 to have antidepressant activity in the rat forced-swim test and mouse suspension test in mice. Subsequently, Shimazaki et al. [129] reported MGS0039 was anxiolytic in the marble-burying test, unlike the mGlu2/3 receptor antagonist LY341495 (the reasons for this are not clear). In support of the hypothesis that mGlu2/3 antagonists are antidepressant, Yoshimizu et al. [130] reported that chronically administered MGS0039 increased cell proliferation (BrdU labeling) in the adult mouse hippocampus. The work of Karasawa et al. [131] suggests that the antidepressant actions of MGS0039 involves activation of AMPA receptors, which drives increases in serotonin neurotransmission. In their study, 2,3-dihydroxy-6-nitro-7-sulfamoyl-benzo(*F*)quinoxaline (NBQX) blocked the antidepressant effects of MGS0039 in the tail suspension test and MGS0039 induced increases in serotonin release in the rat prefrontal cortex. Increases in serotonin neurotransmission subsequent to mGlu2/3 receptor antagonism has also been reported for MGS0039 and LY341495 using electrophysiology [132, 133].

11.2.5 Group III Selective Orthosteric Agonists

L-AP4/L-SOP: Simple bioisosteric replacement of the distal carboxylic acid moiety on glutamic acid has led to novel and interesting group III mGlu selective agonists. The most well studied and notable of these compounds are L-4-phosphono-2-aminobutyric acid (L-AP4) and L-serine-*O*-phosphate (L-SOP) (see Fig. 11.6). Prior to the recognition that mGlu receptors existed, L-AP4 was reported to suppress excitatory transmission in multiple excitatory synapses, including the lateral perforant path [134], mossy fiber pathway [135, 136], lateral olfactory tract [137], and retina [138]. Ganong and Cotman [139] showed that this presynaptic inhibitory action of L-AP4 in the lateral perforant path was also produced by L-SOP. This so-called L-AP4 receptor remained somewhat an enigma until the cloning of mGlu receptor subtypes, when it was recognized that these compounds act as relatively potent and

Figure 11.6 Group III selective orthosteric agonists.

somewhat selective agonists for mGlu4, mGlu6, mGlu7, and mGlu8 receptors (see [140]). As each of the L-AP4-sensitive members of the cloned group III mGlu receptors (e.g., mGlu4, mGlu7, and mGlu8) are found to exist presynaptically in L-AP4-sensitive excitatory pathways, it is possible that in a given synapse one or more of the group III receptors function as negative-feedback receptors that regulate glutamate release. Studies have attempted to understand which L-AP4-sensitive subtype(s) are responsible for suppression of excitatory transmission in specific preparations (see [140, 141]). For example, the L-AP4 receptor in the retina has been suggested to be mGlu6, as this receptor shows selective expression in this tissue [142]. L-AP4 and L-SOP are each nanomolar to low micromolar potent agonists for multiple group III mGlu receptor subtypes, including mGlu4, mGlu6, and mGlu8 (see [8, 140]). As L-AP4 is relatively inactive at cloned group I or group II mGlu receptors, this has made this compound “diagnostic” for the involvement of group III receptors in cellular functions. However, millimolar concentrations of L-AP4 are required to activate mGlu7 receptors, and these concentrations have also been shown to activate cloned mGlu2 and mGlu3 receptors (see [8]). Furthermore, the selectivity of L-SOP across all cloned mGlu receptors needs to be better established. Clearly, better and more subtype selective agonists for group III mGlu receptors than L-AP4 or L-SOP are desirable to study the role of specific group III mGlu receptors in the regulation of excitatory synaptic transmission. In this regard, additional agents targeted at advancing group III mGlu receptor pharmacology have recently been described and are discussed below.

(R,S)-PPG: The phosphono-substituted phenylglycine compound *(R,S)*-4-phosphonophenylglycine [(*R,S*)-PPG], Fig. 11.6] has been shown to be a potent and selective mGlu receptor agonist at each cloned group III receptor subtype with the following order of potency: mGlu8 ($EC_{50} = 0.2 \mu M$) > mGlu6 = mGlu4 ($EC_{50} = 5 \mu M$) > mGlu7 ($EC_{50} = 185 \mu M$). Importantly, (*R,S*)-PPG is relatively inactive at cloned group I and group II mGlu receptors or ionotropic glutamate receptors [143, 144]. Separation of the enantiomers demonstrated that the mGlu8 agonist activity resides exclusively in the (+)-isomer [144]. Similar to other phosphono-amino acids, (*R,S*)-PPG showed micromolar potency at Ca^{2+}/Cl^{-} dependent binding sites in the rat brain. Consistent with other group III agonists such as L-AP4, (*R,S*)-PPG was neuroprotective against N-methyl-D-aspartate (NMDA)-mediated excitotoxicity in cultured neurons in vitro, and when coinjected with NMDA into the rat striatum in vivo. While not efficacious in protecting hippocampal neurons in global or focal ischemia models, [(*R,S*)-PPG]

300 nmol, i.c.v.] decreased quinolinic acid-induced striatal lesion size in the rat [145]. (*R,S*)-PPG was also shown to be fully protective against maximal electroshock seizures in mice when administered i.c.v. (173 nmol) but did not protect when given parenterally (100 mg/kg i.p., or 10 mg/kg i.v.) in the same test. In subsequent studies, (*R,S*)-PPG was anticonvulsant against sound-induced seizures in the DBA/2 mouse [146]. These studies with (*R,S*)-PPG further support a role for group III agonists as novel agents to treat seizure or neurodegenerative disorders (for a review on this subject (see [147]).

DCPG: (*S*)-3,4-Dicarboxyphenyl glycine (Fig. 11.6) represents the first subtype selective mGlu8 receptor agonist with an $EC_{50} = 31$ nM for activation of recombinantly expressed human mGlu8a receptors but no activity at other human mGlu receptor subtypes (1–7) at up to 1000 nM [148]. DCPG appears to be a useful compound to study the pharmacology associated with selective mGlu8 receptors both in vitro and in vivo. For example, DCPG was shown to depress the fast component of the dorsal root-evoked ventral root potential in the neonatal rat spinal cord preparation [148, 149]. Systemic administration of (*S*)-DCPG 30 or 100 mg/kg i.p. in the mouse increased c-Fos expression in certain stress-associated brain regions (central amygdala, paraventricular nucleus of the hypothalamus), and these changes were absent in the mGlu8 receptor knockouts [150]. Moldrich et al. [151] showed that *S*-DCPG was anticonvulsant in the DBA/2 mouse (i.c.v. injection) but that the racemic compound (*R,S*) was more potent, likely due to the AMPA receptor antagonist activity of the *R* isomer. Interestingly, (*R,S*)-DCPG 60–100 mg/kg i.p. had a typical (vs. atypical) antipsychotic profile in mice, but it is not clear if this involves its mGlu8 agonist and/or AMPA receptor activities [152].

ACPTs: Acher et al. [153] have reported on the four stereoisomers of 1-aminocyclopentane-1,3,4-tricarboxylic acid (ACPT). Two of these isomers, ACPT-I and ACPT-III (Fig. 11.6), were micromolar potent agonists for mGlu4a, with weak antagonist activities at mGlu1 and mGlu2. ACPT-I demonstrated anticonvulsant activity in multiple seizure models when given by an i.c.v. route [154]. These compounds may be useful to explore group III mGlu receptors; however, their activity across other glutamate receptor subtypes has not been fully characterized.

11.2.6 Group III Selective Orthosteric Antagonists

In general, group III mGlu receptor antagonists represent the least developed area of mGlu receptor pharmacology. Many agents with group III antagonist activity also possess group II mGlu receptor antagonist activity and/or their profile across all four group III receptors has not been described. Nevertheless, the actions of these agents which block group III mGlu subtypes can be compared to the effects of more selective group II agonists to get an indication of the possible involvement of group III mGlu receptors in native tissues. Furthermore, the ability of a compound to reverse the actions of selective group III agonists such as L-AP4 in native tissue is useful information suggesting group III involvement. With these caveats, certain compounds targeted at these receptors have emerged as useful agents and are discussed below. For a more detailed discussion of the structure–activity relationship of other compounds related to the ones described below, see Schoepp et al. [8].

MAP4/MSOP: (*S*)- α -Methyl-2-amino-4-phosphonobutanoic acid (MAP4) and (*R,S*)- α -methylserine-*O*-phosphate (MSOP) are the α -methyl analogs of the group III selective agonists L-AP4 and L-SOP, respectively (see Fig. 11.7). In the rat

Figure 11.7 Group III selective orthosteric antagonists.

neonatal spinal cord preparation where these compounds were initially described, both were moderately potent group III selective competitive antagonists, in that they selectively reversed the depressant effects of L-AP4 [112, 155–157]. Likewise, in the rat thalamus *in vivo* [158], CA1 region of the hippocampus [159], and hippocampal lateral perforant path [160], MAP4 selectively blocked the actions of L-AP4. Thus, at least in these preparations, there appears to be a group III L-AP4-activated mGlu receptor subtype that is sensitive to MAP4 and/or MSOP. Studies indicate that MAP4 and MSOP are antagonists at mGlu4 receptors. However, the profile of MAP4 and MSOP across all eight receptors is not known, and there are some discrepancies in their activities across different laboratories (see [8]). For example, data in certain preparations suggest that MAP4 may have group II and/or group III mGlu receptor agonist/partial agonist activities. In adult rat cortical slices MAP4 potentially suppressed forskolin-stimulated cAMP formation ($EC_{50} = 0.11 \mu\text{M}$) [114], and in contrast to others [141], Knopfel et al. [113] found MAP4 to be a partial agonist at rat mGlu4a receptors. Thus, the antagonist actions of these agents should not be considered indicative of the involvement of a group III mGlu receptor in physiological or pathological processes involving glutamate.

MPPG: (*R,S*)- α -Methyl-4-phosphonophenylglycine (Fig. 11.7) is the phospho-substituted version of MCPG. As the substitution of the distal carboxy group in glutamate with a phosphono acidic bioisostere (producing L-AP4) leads to group III activity, one could suggest that a similar change to MCPG might produce group III antagonist activity. Indeed, MPPG has been shown to be a group III mGlu receptor antagonist in a number of test systems, as indicated by selective reversal (generally at 50–200 μM concentrations) of the actions of L-AP4 in rat spinal cord [20], the ventrobasal thalamus [161], lateral perforant path of the hippocampus [162], and L-AP4 suppression of forskolin-stimulated cAMP formation in adult rat cortex [163]. However, MPPG appears to act on group II receptors, as at similar or higher concentrations it has been shown to also reverse the actions 1*S*,3*S*-ACPD in the spinal cord [155] and L-CCG-I suppression of forskolin-stimulated cAMP formation in the rat cortex [163]. Studies in recombinant mGlu receptors have shown that MPPG is both a group II and group III mGlu receptor antagonist. It is a moderately potent antagonist at rat mGlu2 and mGlu4 receptors [156, 164–166]. Wu et al. [26] compared its actions across human group III receptors in the same cell line and found that MPPG most potently blocked mGlu8 receptors ($IC_{50} = 47 \mu\text{M}$) followed by mGlu7 ($IC_{50} = 528 \mu\text{M}$) and mGlu4 ($IC_{50} = 540 \mu\text{M}$). Thus, in general, the

usefulness of MPPG is limited by lack of good selectivity and potency for the group III mGlu receptors.

CPPG: (*R,S*)- α -Cyclopropyl-4-phosphonophenylglycine (CPPG) differs from MPPG by the incorporation of a cyclopropyl group at the α carbon rather than a methyl (Fig. 11.7). With this change, the potency of CPPG as an antagonist for both group II and group III mGlu receptors was greatly increased in the rat cerebral cortex. CPPG antagonized L-AP4 and L-CCG-I inhibitions of forskolin-stimulated cAMP formation with IC_{50} values of 2.2 and 46 nM, respectively. However, it only weakly ($K_B = 650 \mu M$) blocked group I agonist stimulations of phosphoinositide hydrolysis [167]. In membranes prepared from rat mGlu4a-expressing cells, CPPG displaced 3H -AP4 binding ($K_i = 23 \mu M$) with about three fold greater potency than MPPG or MAP4 [168]. However, the micromolar potency at mGlu4a receptors is at odds with nanomolar antagonist potency observed against L-AP4 second messengers in rat brain.

11.3 SUBTYPE SELECTIVE ALLOSTERIC POTENTIATORS AND ANTAGONISTS

The availability of recombinant mGlu subtypes, effective cellular expression strategies, and advances in functional assay formats for G-protein-coupled receptors have allowed for the high-throughput screening of compound libraries against individual mGlu receptor subtypes. This approach has resulted in the identification of a number of structurally novel non-amino acid allosteric modulators of the mGlu receptors. In most cases the positive allosteric modulators and allosteric antagonists act within the heptahelical (7-TM) domain of these receptors, rather than the glutamate recognition site within the amino-terminal segment. Thus, the antagonists are noncompetitive against glutamate and the positive allosteric modulators do not displace orthosteric ligands.

The majority of positive allosteric modulators characterized have acted as potentiators of glutamate in both clonal cell lines and native tissue assays, rather than simply as allosteric agonists. Rather, the potentiators typically act to enhance the binding affinity of orthosteric agonists, increasing the sensitivity of a mGlu-mediated effect in clonal cells and native tissues. Interestingly, many of the potentiators and allosteric antagonists alike demonstrate a high degree of mGlu subtype selectivity even against highly related mGlu receptors within the same group. Thus they may serve as highly useful pharmacological tools for delineating mGlu subtype-specific function(s). In addition, compounds with mixed actions (potentiator vs. antagonist) and unique selectivity profiles against mGlu subtypes across groups I, II, and III have been discovered. Examples of these very novel and important pharmacological tools for select receptors in groups I, II, and III are provided below.

11.3.1 mGlu1 Allosteric Potentiators

The first mGlu receptor potentiators described were for the mGlu1 subtype, for example, RO 67-7476 and RO 67-4853 (Fig. 11.8; (9*H*-xanthene-9-carbonyl)-carbamate butyl ester and (*S*)-2-(4-fluoro-phenyl)-1-(toluene-4-sulfonyl)-pyrrolidine,

Figure 11.8 mGlu1 allosteric potentiators.

respectively] [169]. Both act to enhance a submaximal effect of glutamate or the orthosteric agonist DHPG in the rat mGlu1a receptor expressing cells with potentiation EC_{50} values of 174 and 69 nM for RO 67-7476 and RO 67-4853, respectively. Each is selective for the rat mGlu1 receptor versus mGlu5, mGlu2, mGlu4, and mGlu8 receptors, but interestingly, RO 67-7476 did not show potentiation of the recombinant human mGlu1a receptor, while RO 67-4853 was equipotent and efficacious at both the rat and human receptors. Systematic testing in chimeric and point mutants of the group I receptors localized the species selectivity to a single amino-acid change within transmembrane region (TM) 5 where a valine in the rat mGlu1a receptor is a leucine in both the human mGlu1 and rat mGlu5 receptors. The group went on to show that this change (valine to leucine in TM5) in combination with two changes in TM3 (a serine to phenylalanine and cystine to serine) accounts for the subtype selectivity for rat mGlu1 versus mGlu5 as well. Though activity for both RO 67-7476 and RO 67-4853 was confirmed in native tissue preparations from rat cerebellum or hippocampus, the utility of these novel pharmacological tools for in vivo behavioral and biochemical applications remains unknown. However, a recent patent application disclosure from Hoffman-LaRoche describes a series of related oxazol-2-yl-amide xanthenes with less than 200 nM potency as mGlu1 potentiators and decreased metabolism in liver microsomes [170, 171]. These new allosteric modulators may well represent useful tools in studying the effects of mGlu1 potentiators.

11.3.2 mGlu1 Allosteric Antagonists

CPCCOEt: 7-Hydroxyiminocyclopropan[b]chromene-1 α -carboxylic acid (Fig. 11.9) exhibits micromolar potency ($IC_{50} \sim 23 \mu M$) as a noncompetitive inhibitor of functional responses at human mGlu1 receptors but did not exhibit any appreciable activities at mGlu2, mGlu4a, mGlu5a, mGlu7b, or mGlu8a receptors when tested at up to 100 μM [172–175]. CPCCOEt does not directly interact at the glutamate binding domain, as it did not displace 3H -glutamate binding to the receptor [175]. Interestingly, it appears to interact at a region downstream from the N-terminal extracellular domain, specifically involving residues Thr815 and Ala818 within TM-VII of mGlu1, as introduction of these residues into the mGlu5a receptor introduced sensitivity for CPCCOEt inhibition to this receptor. Likewise, substitution of the corresponding mGlu5a residues for the critical residues on mGlu1 resulted in loss of CPCCOEt inhibition [175]. These studies with CPCCOEt illustrate a highly specific molecular interaction of this agent at a site distal to the glutamate binding region.

Figure 11.9 mGlu1 allosteric antagonists.

Since the recognition of CPCCOEt as an allosteric antagonist, several highly potent and structurally distinct mGlu1 negative modulators have been described. For instance, Fig. 11.9 illustrates three such mGlu1 antagonists with nanomolar potency in functional assays (calcium mobilization) using mGlu1-expressing cells: 160 nM BAY36-7620 [(3a*S*,6a*S*)-6a-naphthalen-2-ylmethyl-5-methyliden-hexahydro-cyclopental[*c*]furan-1-on] [176]; 3 nM JNJ16259685 [(3,4-dihydro-2*H*-pyrano [2, 3]*b* quinolin-7-yl) (*cis*-4-methoxycyclohexyl) methanone] [177]; and 16 nM IC₅₀ 3,5-DiMePPP [3,5-dimethyl pyrrole-2,4-dicarboxylic acid 2-propyl ester 4-(1,2,2-trimethyl-propyl) ester] [178]. All three were characterized and found to be non-competitive antagonists, with at least 100-fold selectivity for mGlu1 receptor versus the other mGlu receptors examined. BAY36-7620 did not displace the mGlu1 orthosteric agonist [³H]-quisqualate and the binding domain for BAY36-7620 and 3,5-DiMePPP was localized to the transmembrane region by testing with chimeric receptors. Furthermore, JNJ16259685 was found to displace with high affinity a previously characterized radiolabeled allosteric antagonist [³H]-R214127 (1-(3,4-dihydro-2*H*-pyrano[2,3-*b*]quinolin-7-yl)-2-phenyl-1-ethanone) [177].

In vivo, BAY36-7620 was efficacious in an acute subdural hematoma rat model (0.01 mg/kg/h i.v. infusion) as well as protective against pentylenetetrazole-induced convulsions in mice (10 mg/kg i.v.) [179]. 3,5-DiMePPP was efficacious in multiple pain models at 0.3–10 mg/kg i.p., including a mouse formalin pain model, a rat carrageenan pain model, and a rat chronic nerve injury pain model [178]. Similarly, utilizing an ex vivo autoradiography method, JNJ16259685 (0.04 mg/kg s.c.) displaced cerebellar binding of the allosteric radiolabeled antagonist [³H]-R214127 [177]. Given these results, the three compounds promise to be very useful pharmacological tools in determine the importance of mGlu1 antagonism in multiple disease states.

11.3.3 mGlu2 Allosteric Potentiators

The first positive allosteric modulators for the mGlu2 receptor are typified by the (3-pyridinyl)methylsulfonamide 4-MPPTS or LY487379 shown in Fig. 11.10

Figure 11.10 mGlu2 allosteric potentiators.

(2,2,2-trifluoro-*N*-[4-(2-methoxyphenoxy)phenyl]-*N*-(3-pyridinylmethyl)ethanesulfonamide) [180, 181]. As with the mGlu1 potentiators, 4-MPPTS and its close analog 3-MPPTS (2,2,2-trifluoro-*N*-[3-(2-methoxyphenoxy)phenyl]-*N*-(3-pyridinylmethyl)ethanesulfonamide) act to increase the potency of orthosteric agonists as indicated by glutamate curves shifting leftward in functional assays and increased affinity of mGlu2 agonists such as [³H]-DCG-IV [2*S*,1'*R*, 2'*R*, 3'*R*-2-(2', 3'-dicarboxycyclopropyl) glycine] [181, 182]. Here, as well, testing in chimeric and point mutation altered mGlu2 receptors has indicated that the binding domain of the potentiators is within the transmembrane domain with a critical role for an asparagine in TM5 [181].

Structure-activity relationships (SAR) within this series of compounds has led to some very potent potentiators, such as cyPPTS (24 nM; 2,2,2-trifluoro-*N*-[3-(cyclopentyloxy)phenyl]-*N*-(3-pyridinylmethyl)ethanesulfonamide) [183]. Indeed, cyPPTS typifies one important aspect of potentiators versus orthosteric agonists, namely an ability to function in a state-dependent manner. In rat brain slices, corticostriatal excitatory postsynaptic potentials (EPSPs) could be inhibited with the mGlu2/3 receptor orthosteric agonist LY354740 irrespective of frequency of axonal stimulation.

However, EPSPs are inhibited with the potentiator cyPPTS only when the higher frequency stimulus was given (conditions of more glutamate release) [182]. Thus, potentiators might be expected to selectively impact neuronal pathways only under conditions of excessive glutamate release (i.e., potentially disease states) while not affecting resting states (i.e., fewer side effects).

In animal models, mGlu2 potentiators such as 4-MPPTS, 2,2,2-TEMPS (2,2,2-trifluoro-*N*-[3-(1-methyl-butoxy)phenyl]-*N*-(3-pyridinylmethyl)ethanesulfonamide), 4- APPEs (*N*-[4-(4-carboxyamidophenoxy)phenyl]-*N*-(3-pyridinylmethyl)ethanesulfonamide), and CBiPES (*N*-[4'-cyano-biphenyl-3-yl]-*N*-(3-pyridinylmethyl)ethanesulfonamide) have all shown efficacy in one or more models of anxiety and/or psychosis. For instance, when administered subcutaneously both 4-MPPTS and APPEs were anxiolytic-like in a rat potentiated startle paradigm, as was CBiPES in reducing stress-induced hyperthermia in mice, both animal models of anxiety disorders [180, 182]. CBiPES was also efficacious in a PCP-induced locomotor activity model commonly used to test for antipsychotics [182], and pretreatment with 2,2,2-TEMPS was effective in limiting the norepinephrine dialysate released by ketamine treatment in the hippocampus of rats [184].

More recently a second chemical series of mGlu2 potentiators has been described. This second series is typified by the phenyl-tetrazolyl acetophenone 1-(2-hydroxy-4-{4-[4-(2*H*-tetrazol-5-yl)-phenoxy]-butoxy}-3-propyl-phenyl)ethanone (compound **1**, Fig. 11.10) [185, 186]. Compound **1** is reported to be a selective mGlu2 potentiator with an EC₅₀ of 300 nM and no allosteric or orthosteric activity against mGlu3, 1, 4, 5, 7, or 8. However, when given to rats at 20 mg/kg i.p. compound **1** showed very low brain-to-plasma ratios. It should also be cautioned that some phenyl-tetrazole acetophenones such as compound **1** are reported to be antagonists at the leukotriene receptor cystinyl leukotriene 1 (CysLT1) subtype normally activated by leukotriene D4 (LTD4) and may have some activity at one or more peroxisomal proliferation activating receptors (PPARs). Recently Pinkerton and co-workers [187–189] reported on related molecules with similar potencies to **1**, including (±)-6,7-dichloro-2,3-dihydro-2-propyl-5-[(3-[(4-pyridinylthio)methyl]phenyl)methoxy]-1*H*-Inden-1-one (compound **2**, Fig. 11.10) and (±)-5-[(4'-carboxy-[1,1'-biphenyl]-3-yl)methoxy]-2,3-dihydro-6,7-dimethyl-2-pentyl-1*H*-Inden-1-one (compound **3**, Fig. 11.10). In contrast to compound **1**, the brain penetration for compounds **2** and **3** were greatly improved at 2 h with a 20 mg/kg i.p. dose. When tested in a ketamine-induced locomotor activity model of psychosis a 40-mg/kg i.p. dose of compound **2** partially reversed the ketamine response [188], while a 20 mg/kg i.p. dose of compound **3** was fully efficacious. More experiments are needed, but these initial results suggest that CBiPES and compound **3** may be useful pharmacological tool to explore the utility of mGlu2 potentiators.

11.3.4 mGlu2/3 Allosteric Antagonists

To date only one chemical series with negative allosteric activity (i.e., noncompetitive antagonism) has been identified for the group II mGlu receptors. Based on the available patent applications and a Society for Neuroscience abstract, RO 71-8218 (Fig. 11.11; 8-(4-fluoro-phenylethynyl)-7-hydroxy-4-(3-[1,2,3]triazol-1-yl-phenyl)-1,3-dihydro-benzo[*b*][1,4]diazepin-2-one) [190, 191] shows nanomolar potency as a non-competitive antagonist against mGlu2 and mGlu3 receptors and was selective versus

Figure 11.11 mGlu2 allosteric antagonists.

mGlu1, 4, 5 and 8 as well as ionotropic glutamate receptors. Interestingly RO 71-8218 also partially displaced the binding of an mGlu2/3 orthosteric agonist [^3H]-LY354740, suggesting a possible modulation of the glutamate site by binding to a distal allosteric site. Alternatively, RO 71-8218 could share a partially overlapping binding domain with the glutamate site in the amino-terminal segment. Here, again, too little information is available to definitively determine the mechanism of antagonism (allosteric vs. orthosteric) or the utility of these antagonists as pharmacological tools in vitro or in vivo.

11.3.5 mGlu4 Allosteric Potentiators

Progress in the identification and characterization of allosteric modulators for the group III mGlu receptors (4, 6, 7, and 8) has been somewhat slower in coming, although an antagonist of the mGlu7 receptor (see below) and a handful of mGlu4 potentiators have been described. Interestingly two of the mGlu4 potentiators were first characterized as mGlu5 receptor allosteric antagonists (vide infra), namely 2-methyl-6-(2-phenylethenyl)pyridine (SIB-1893) and MPEP (see Fig. 11.14 below [192]). However, subsequent testing found that both are also mGlu4 potentiators though much less potent compared to their nanomolar potency as allosteric antagonists at the mGlu5 receptor. Nevertheless, both SIB-1893 and MPEP increase the potency and/or maximal effect of the orthosteric agonists, such as L-AP4 and L-glutamate, in a clonal cell line expressing human mGlu4 receptors. As anticipated with an allosteric mechanism neither SIB-1893 nor MPEP displaced the orthosteric agonist [^3H]-L-AP4. Rather, 50–100 μM SIB-1893 significantly increased the affinity of [^3H]-L-AP4, similar to what has been reported for the mGlu2 potentiators.

Interestingly, another structural class of mGlu4 potentiators is also structurally related to an allosteric group I antagonist. Specifically CPCCOEt is an allosteric mGlu1 antagonist (as described above; Fig. 11.9) while a closely related structure, PHCCC (*N*-phenyl-7-(hydroxyimino)cyclopropa[*b*]chromen-1 α -carboxamide; Fig. 11.12) is an

Figure 11.12 mGlu4 allosteric potentiator.

allosteric potentiator of mGlu4 [193, 194]. PHCCC is not, however, selective for the mGlu4 receptor, showing similar micromolar potency for mGlu1 antagonism and less than 10-fold selectivity for antagonism of mGlu2, mGlu8, and mGlu5. In native tissue systems, PHCCC was neuroprotective in primary mixed neuronal/glial cortical cultures against NMDA- or β -amyloid protein (25–35)-induced toxicity [193] and potentiated the inhibitory response of L-AP4 in striatal pallidal synapses from rat brain slice preparations [194]. Given the latter effect, Marino and co-workers [194] went on to demonstrate that direct intracerebroventricular injection of PHCCC, but not CPCCOEt, dramatically reversed the akinesia induced by acute dopamine depletion with reserpine, a model of Parkinsonism-related motor deficits. Similarly, direct injection of PHCCC into the basolateral amygdala of rats was effective in an anxiety model, the Vogel conflict drinking paradigm [195], though a partial response was also seen with the mGlu1 antagonists CPCCOEt, and a small but statistically insignificant decrease in shock threshold with both compounds makes interpretation of the results somewhat difficult. Taken together, the available results with PHCCC do suggest potentiators of mGlu4 hold therapeutic promise. However, more potent, selective, and systemically active mGlu4 potentiators will need to be discovered and characterized before any definitive conclusions can be made.

11.3.6 mGlu5 Allosteric Potentiators

3,3'-Difluorobenzaldazine (DFB; Fig. 11.13) was the first potent and selective positive allosteric modulator of mGlu5 to be described [196]. At concentrations up to 100 μ M, DFB is devoid of agonist activity at recombinant human mGlu5 receptors. However, in the presence of submaximal (300 nM; approximate EC_{10} concentration) glutamate, DFB produced a concentration-dependent activation of this receptor with an apparent EC_{50} value of 2.6 μ M and a maximal 3.1-fold potentiation of this submaximal glutamate challenge. Furthermore, DFB induces a 2-fold leftward shift of the orthosteric agonist (glutamate, 3,5-dihydroxyphenylglycine or quisqualate) concentration–response curves at recombinant human, recombinant rat, and native tissue (hippocampal) rat mGlu5 receptors *in vitro*. As expected, DFB did not influence the binding of the orthosteric site radioligand [3 H]-quisqualate but was partially effective (51% maximal efficacy) in displacing [3 H]-methoxy-PEPy (2-phenylethynylpyridine) binding from its TM7 binding site [197]. At 100 μ M, DFB displays mGlu4 and mGlu8 antagonist activity. Interestingly, minor structural modification of DFB led to both a noncompetitive mGlu5 antagonist and a ligand that displays neutral cooperativity with orthosteric agonists [196].

Figure 11.13 mGlu5 allosteric potentiators.

Another structurally distinct mGlu5 potentiator, CPPHA (*N*-(4-chloro-2-[(1,3-dioxo-1,3-dihydro-2*H*-isoinol-2-yl)methyl]phenyl)-2-hydroxybenzamide; Fig. 11.13) [198], was identified as a mGlu5 potentiator (human mGlu5 EC_{50} = 393 nM; 7-fold leftward shift in the glutamate concentration–response curve. CPPHA increased NMDA currents in hippocampal CA1 pyramidal cells in the presence of submaximal DHPG and increased depolarization of subthalamic neurons, again in the presence of submaximal DHPG. Interestingly, CPPHA does not influence the binding of either [3 H]-quisqualate or [3 H]-methoxy-PEPy, suggesting a unique site of action. Like DFB, CPPHA also demonstrates antagonist activity at both mGlu4 (IC_{50} = 12.7 μ M) and mGlu8 (IC_{50} = 7.5 μ M). The utility of CPPHA as a tool to study mGlu5 function may be limited owing to significant off-target cross reactivity with a number of non-glutamate targets at submicromolar concentrations, including PDE₆ (phosphodiesterase), δ - and κ -opiate receptors, and hERG (Human Ether-a-go-go Related Gene) potassium channels [198].

Most recently, CDPPB [3-cyano-*N*-(1,3-diphenyl-1*H*-pyrazol-5-yl)benzamide; Fig. 11.13] has been reported to potentiate mGlu5 receptors with high potency (human mGlu5 EC_{50} = 10–27 nM) [199, 200] and a 9-fold leftward shift of the glutamate concentration–response curve [200]. CDPPB did not influence the binding of the orthosteric site radioligand [3 H]-quisqualate but was fully effective in displacing [3 H]-methoxy-PEPy binding from its TM7 binding site (K_i \sim 2 μ M). CDPPB produces an apparent mGlu5 agonist effect at concentrations significantly above those required for potentiator activity (agonist EC_{50} \sim 10 μ M, E_{max} \sim 35–35% of maximal glutamate response). The agonist effect of CDPPB was not blocked by the orthosteric antagonist LY341495 (see Fig. 11.5) but was fully inhibited by the allosteric antagonist MPEP (see Fig. 11.14). While CDPPB possesses weak antagonist activity versus mGlu8 (IC_{50} \sim 10 μ M) [199], it appears to be significantly more selective than CPPHA, possessing greater than 1 μ M potency (IC_{50} or K_i) against a broad panel of receptors, transporters, ion channels, and enzymes [200]. CDPPB demonstrates poor (\sim 3%) oral bioavailability in rats; however, following subcutaneous administration at doses of 10–60 mg/kg, brain levels of CDPPB (110–270 nM) are in the range of those that are fully efficacious in potentiating submaximal

Figure 11.14 mGlu5 allosteric antagonists.

glutamate responses in vitro. In behavioral studies, CDPPB (10 mg/kg s.c.) had no effect on spontaneous locomotor activity in rats but was effective in decreasing amphetamine-induced ambulations [200]. Furthermore, CDPPB (10 and 30 mg/kg s.c.) had no effect on baseline acoustic startle responding but reversed amphetamine-induced deficits in prepulse inhibition (PPI) of startle [199, 200]. These results are consistent with the hypothesis that potentiation of mGlu5 receptors represents a novel approach for treatment of schizophrenia.

11.3.7 mGlu5 Allosteric Antagonists

SIB-1757 [6-methyl-2-(phenylazo)-3-pyridinol] and SIB-1893 [(*E*)-2-methyl-6-(2-phenylethenyl)pyridine] (Fig. 11.14) were the first noncompetitive antagonists of mGlu5 receptors to be described [201]. These were discovered by high-throughput screening of compounds for their ability to inhibit glutamate-induced intracellular calcium mobilization in a cell line expressing human mGlu5a receptors. SIB-1757 and SIB-1893 inhibit glutamate responses at human mGlu5a receptors with IC_{50} values of 0.37 and 0.29 μ M, respectively. Notably, neither analog elicited effects on human isoforms of mGlu1, mGlu2, mGlu3, mGlu4, mGlu6, mGlu7, or mGlu8 receptors at concentrations up to 100 μ M, nor were they active at recombinant AMPA, kainate, or NMDA receptors when tested up to 30 μ M. Consistent with their mGlu5 selectivity profile at human recombinant receptors, both SIB-1757 and SIB-1893 potently antagonized 3,5-DHPG-induced phosphoinositide hydrolysis in rat brain regions expressing high levels of mGlu5 (hippocampus and striatum) but had no effect in the rat cerebellum, a region primarily expressing mGlu1 receptors.

MPEP [2-methyl-6-(phenylethynyl)pyridine; Fig. 11.14] was discovered following structural modification of SIB-1893, in which the alkenyl linker group was replaced by an alkyne [202]. It is approximately 10 times more potent than either SIB-1757 or SIB-1893, displaying an IC_{50} value of 32 nM in human mGlu5a-expressing cells and 15 nM against 3,5-DHPG-stimulated phosphoinositide hydrolysis in the neonatal rat hippocampus. MPEP blocked constitutive mGlu5 activity in cells overexpressing recombinant mGlu5 receptors, suggesting an inverse agonist mode of action [203]. The binding site for MPEP within the heptahelical domain of mGlu5 was unambiguously identified through a series of elegant experiments utilizing both mGlu1/5 chimeric receptors and mGlu5 single-amino-acid mutants [203, 204]. From these, it appears that MPEP binds within a pocket formed by residues projecting from transmembrane-spanning domains III, V, VI, and VII.

MPEP was initially found to be highly selective for mGlu5 receptors, with high micromolar concentrations producing no statistically significant effects across other cloned mGlu or iGlu receptor subtypes [202]. Subsequent accounts, however, have shown that high concentrations of MPEP (above 10 μ M) can antagonize native NMDA receptor function [205] and potentiate mGlu4 receptors [192]. The NMDA antagonist property of MPEP may at least be partially responsible for observed neuroprotective properties of this molecule [205, 206]. More recently, MPEP has been reported as a relatively potent inhibitor of norepinephrine uptake ($IC_{50} \sim 3 \mu$ M [207]), monoamine oxidase A (MAO_A, $IC_{50} = 8 \mu$ M [197]), and cytochrome P₄₅₀ isoform CYP1A2 (cytochrome P₄₅₀1A2) ($K_i = 0.4 \mu$ M [208]). Nevertheless, owing to its excellent potency, good (though not absolute) pharmacological selectivity, and functional

antagonist activity at mGlu5 receptors following systemic administration [202], MPEP remains a highly valuable tool for evaluating mGlu5 receptor function under physiological and pathophysiological conditions. It has been widely studied as an effective treatment in models of anxiety [90, 209–212], pain [34, 213–221], neuroprotection [205, 206, 222–225], Parkinson's disease [226–229], Huntington's disease [102], and drug abuse [230–233]. The discovery, pharmacology, and activity of MPEP in various disease models have been reviewed [234–237].

In an effort aimed at improving the biochemical selectivity and aqueous solubility of MPEP, 3-[(2-methyl-1,3thiazol-4-yl)ethynyl]pyridine (MTEP; Fig. 11.14) was discovered [197]. MTEP displays mGlu5 binding affinity ($K_i = 16$ nM), functional antagonist potency ($IC_{50} = 5$ nM), and receptor occupancy (median effective dose $ED_{50} = 1$ mg/kg i.p.) comparable to MPEP but with significantly reduced NMDA antagonist ($IC_{50} > 100$ μ M) and MAO_A inhibitory ($IC_{50} = 30$ μ M) activity. More extensive profiling demonstrated excellent selectivity versus other mGlu and iGlu receptor subtypes ($IC_{50} > 10$ μ M) including mGlu4, where it was inactive as a potentiator at concentrations up to 100 μ M [238]. MTEP was also inactive against a broad panel of CNS receptors when screened at 10 μ M [238]. MTEP has a lower brain-to-plasma ratio than MPEP and when dosed systemically is slightly more potent than MPEP in decreasing conditioned responding in the fear-potentiated startle model in rats (MTEP $ED_{50} = 1$ mg/kg i.p. vs. MPEP $ED_{50} = 5$ mg/kg i.p.). MTEP is active acutely in the Geller–Seifter conflict test at doses (3 and 10 mg/kg i.p.) that correspond to mGlu5 receptor occupancy of greater than 90%. At acute doses up to 30 mg/kg, no motor impairment (rotarod) was observed. Curiously, the anxiolytic efficacy of MTEP in the Geller–Seifter model was abolished following three daily (3-mg/kg i.p.) doses. This is in contrast to the maintained anxiolytic activity in the Vogel conflict model for either MPEP [211] or MTEP [239] following 7 days repeat dosing. MPEP also maintained efficacy in the olfactory bulbectomized rat model of depression following repeat dosing for 14 days. The anxiolytic effects of either MPEP [212] or MTEP [239] were not reversed by flumazenil, indicating a GABA-independent mechanism of anxiolysis. However, the anxiolytic (neuropeptide Y) effects of MPEP could be fully blocked by an intra-amygdala dose of the NPY1 (neuropeptide Y) antagonist BIBO 3304 [(R)-N-[[4-(aminocarbonylaminoethyl)phenyl]-methyl]-N²-(diphenylacetyl)-arginamide trifluoroacetate] indicating a role for amygdala NPY signaling in the anxiolytic effects of mGlu5 antagonists. The combination of non-efficacious doses of both MTEP and diazepam resulted in full anxiolytic efficacy, suggesting a possible synergy between mGlu5 antagonist and GABA_A agonist mechanisms [239]. Additional diarylalkynes related to MPEP and MTEP have recently been described [240, 241] as have a number of useful radioligands [197, 242–244].

A number of non-alkyne-containing mGlu5 receptor antagonists have been recently described [245–247]. 2-(3-Methoxy-4-pyridin-2-yl-phenyl)benzoxazole (compound **4**, Fig. 11.14) was described as a potent ($IC_{50} = 41$ nM, $K_i = 159$ nM) and orally bioavailable ($F = 100\%$) mGlu5 antagonist. However, this analog and others from the series demonstrated only modest receptor occupancy following intraperitoneal administration at 10 mg/kg and were inactive in the fear-potentiated startle model of anxiety. 1,3-Diaryl-5-membered ring heterocycles exemplified by 3-fluoro-5-(5-pyridin-2-yl-tetrazol-2-yl)benzonitrile (compound **5**, Fig. 11.14) are potent and selective mGlu5 antagonists (mGlu5 $IC_{50} = 70$ nM, $K_i = 190$ nM) [246]. Compound **5** displays excellent rat bioavailability ($F = 100\%$), receptor occupancy ($ED_{50} = 3$ mg/kg p.o.), and efficacy in the fear-potentiated startle

Figure 11.15 mGlu7 allosteric antagonist.

model of anxiety ($ED_{50} = 5.4 \text{ mg/kg p.o.}$); however, apparent tolerance to the anxiolytic effect of **5** in this model was observed, and this compound was also found to be a relatively potent inhibitor ($IC_{50} = 3.8 \mu\text{M}$) of CYP1A2 in vitro [247]. An effort to reduce the CYP1A2 activity of compounds related to **5** led to the discovery of the more highly optimized variant 3-fluoro-5-[5-(5-methyl-1*H*-imidazol-2-yl)-tetrazol-2-yl]benzonitrile (compound **6**, Fig. 11.14: mGlu5 $IC_{50} = 77 \text{ nM}$; $K_i = 19 \text{ nM}$; $F = 22\%$; 97% mGlu5 receptor occupancy at 10 mg/kg, i.p. ; Cyp1A2 $IC_{50} = 70 \mu\text{M}$).

11.3.8 mGlu7 Allosteric Antagonists

Patent applications claiming mGlu7 receptor antagonists have appeared [248, 249]. In particular, 3-(2-methoxy-phenyl)-5-methyl-6-phenyl-5*H*-isoxazolo[4,5-*c*]pyridin-4-one (compound **7**, Fig. 11.15) is reported to antagonize the L-AP4- (Fig. 11.6) induced calcium response in CHO cells expressing recombinant mGlu7 receptors with an IC_{50} value of 7.65 nM .

11.4 FUTURE PERSPECTIVES

Compared to the early 1990s when the first cloned receptor was elucidated, much progress has been made on the pharmacology of mGlu receptors. Advances in the discovery of new agents now include many nanomolar potent compounds with relatively high mGlu receptor selectivity. This includes group I (mGlu1/5) and group II (mGlu2/3) selective orthosteric agonists and antagonists. Some of these compounds (i.e., DCG-IV, LY354740, LY341495) have been useful as high-affinity radioligands, in performing receptor modeling, in investigating mGlu receptor expression levels and receptor regulation, and in determining the relative affinities of compounds for mGlu receptor binding sites in cells expressing cloned receptors and in the rat brain. A number of noncompetitive allosteric antagonists for specific receptor subtypes have now been described and represent great new tools for target validation studies to drive potential future clinical investigations (e.g., CPCCOEt or JNJ16259685 for mGlu1 and MPEP for mGlu5). These agents have also been useful for investigating critical receptor-ligand interactions and have enhanced the understanding of mGlu receptor structure and function. Systemically active pharmacological tools (e.g., LY354740, LY379268, MPEP) have been described that have enabled the exploration in animals of the potential therapeutic applications of mGlu receptor ligands.

From this work, a number of promising therapeutic targets have now been elucidated and are being pursued. Both orthosteric and allosteric mGlu active

compounds are being optimized as drug candidates and have begun moving into the clinic. The most advanced of these include (1) mGlu2/3 receptor agonists as novel anxiolytics and antipsychotics (clinical information is now known), (2) mGlu5 receptor antagonists for anxiety, pain, and drug abuse (optimized compounds and clinical ligands have been disclosed), (3) mGlu1 receptor antagonists for pain and possibly anxiety or epilepsy (optimized compounds and potential clinically useful ligands have been reported), (4) mGlu2 receptor potentiators for stress-related disorders and psychosis (optimization of compounds have been reported), and (5) earlier but promising targets where tools are beginning to establish the biology and uses (mGlu1 potentiators; various mGlu4, mGlu7, and mGlu8 selective compounds).

In summary, the rapid progress made in mGlu pharmacology is remarkable when compared to other areas of neuropharmacology. In a relatively short period of time (about a decade), there are now many highly potent and subtype selective agents, and some are already advancing into the clinic. In part, this may be driven by the structural heterogeneity of the glutamate binding pocket across subgroups and at the allosteric sites across subtypes, along with new technologies for drug discovery (molecular modeling, screening, transgenic animals). Furthermore, the dominant role of glutamate in the physiology/pathophysiology of the nervous system coupled with the more modulatory role of mGlu receptors makes this a promising area for novel therapeutic applications.

Although the human central nervous system (CNS) is undoubtedly a marvel of implementation of cellular systems, composed of roughly 10^{13} neurons each making thousands of synaptic connections, their functional output can be expressed in terms of a balance between excitatory and inhibitory synaptic activity. Approximately one-third of brain synapses use γ -aminobutyric acid (GABA) as the inhibitory neurotransmitter [1–3]. Experiments carried out during the 1950s and 1960s suggested that GABA has an inhibitory effect in the invertebrate [4–6] and the vertebrate CNS [7–15]. The molecular diversity of type A GABA (GABA_A) receptor subunit genes probably evolved by a process of duplication and translocation of an ancestral gene, leading to modern-day gene clusters distributed on different human chromosomes [16–18].

L-Glutamic acid decarboxylase (GAD) catalyzes the conversion of L-glutamate to GABA via α decarboxylation resulting in the accumulation and storage of GABA within inhibitory neurons [5, 19, 20]. Upon arrival of an action potential at the nerve terminal, the presynaptic membrane depolarizes inducing the opening of voltage-gated Ca^{2+} channels. Influx of Ca^{2+} ions through these channels increases its intracellular concentration and triggers the fusion of synaptic vesicles containing GABA with the presynaptic membrane. When released into the synaptic cleft GABA freely diffuses within the 20-nm synaptic cleft and binds to both post- and presynaptic receptors. Termination of synaptic transmission is achieved by clearing the neurotransmitter by a combination of diffusion out of the cleft and active transport into contiguous neuronal and/or glial cells [21].

Once recaptured by the neuron, GABA can be further transported into synaptic vesicles by vesicular GABA transporters (VGATs) or degraded by the enzyme GABA aminotransferase to succinic semialdehyde [22]. Different plasma membrane transporters are responsible for high-affinity uptake of GABA into neuronal cells. These membrane-bound transport proteins are dependent on the Na^+ transmembrane gradient and may require either Cl^- or K^+ for activity [23–25].

The accumulation of intraneuronal GABA into storage vesicles theoretically increases the potential concentration gradient across the plasma membrane by compartmentalization of releasable GABA, protecting it from leakage and/or intraneuronal metabolism.

12.1 TRANSPORTERS

Uptake experiments performed in PC12 cells transfected with VGAT complementary deoxyribonucleic acid (cDNA) indicate that GABA has a low affinity for VGAT ($K_m = 5.5 \text{ mM}$) [26]. Studies with native brain synaptic vesicles suggest that a common transporter is responsible for the vesicular accumulation of both GABA and glycine [27]. In situ hybridization and immunohistochemical experiments show that VGAT is expressed in GABAergic and glycinergic neurons [26, 28–30], supporting the idea that VGAT is a neuronal vesicular transporter for both GABA and glycine. Some GABAergic terminals are devoid of VGAT immunoreactivity [29, 30], suggesting that other vesicular GABA transporters exist.

Different plasma membrane neurotransmitter transporters are responsible for the active movement of GABA into neuronal cells. Such transmembrane transport proteins are Na^+ - and Cl^- -dependent symporters [23–25]. Four classes of GABA transporters responsible for the high-affinity uptake of GABA have been identified thus far: the GABA transporters GAT1 [31–33], GAT2 [32], and GAT3 [34, 35] and a betaine/GABA transporter BGT1 [36, 37] with specific cellular and subcellular distribution [38–40]. GAT1 is expressed in both neurons and astrocytes [41–45]. In addition, GAT1 is synthesized in glutamatergic pyramidal cells of the hippocampus and cerebral cortex [41, 46]. GAT2 is expressed by arachnoid and ependymal cells [47, 48] and GAT3 is found in glial cells [44, 45, 49].

Experiments performed in LLCPK-1 and MDCK-1 epithelial cells transfected with GAT1 cDNA indicate that GAT1 is present only at the apical domain of the transfected epithelial cell [50]. This localization is the topological equivalent of the nerve terminal [51]. Immunohistochemical studies also indicate that GAT1 localization is restricted to axon terminals [39, 47].

GABA transporters have 12 transmembrane (TM) domains linked by hydrophilic loops with the amino and carboxyl termini residing inside the cell [52–54]. Mutagenesis studies suggest that the highly conserved TM1 and TM3 are important for the interaction of the transporters with their substrates [55–60]. TM2 seems to play a role in the formation of oligomers during biosynthesis and targeting to the plasma membrane [61].

Although the main function of neuronal GABA transporters is the clearance of GABA from the synaptic cleft, the transporters also appear to be involved in brain development. The blockade of GAT1 activity in early postnatal hippocampal slices leads to a marked enhancement of GABA_A receptor-mediated spontaneous oscillations of neuronal populations or “giant depolarizing potentials” [62]. These synchronous network events seem to be involved in the maturation of neuronal circuits [63–65]. Whereas GAT2 may play an important role in brain development, in adult brain GAT2 participates in metabolic processes together with BGT1 and is involved in transport of GABA across the blood–brain barrier [66, 67].

The function of GABA transporters can be modulated by Ca^{2+} /calmodulin-dependent protein kinase, protein kinase C (PKC), and cAMP-dependent protein kinase A (PKA) [68–70]. PKC activation markedly increases the activity of GAT1 when it is expressed in *Xenopus* oocytes, and this effect is associated with a shift in GAT1 subcellular localization from intracellular vesicles to the plasma membrane [70, 71]. Site-directed mutagenesis studies reveal that the redistribution of this GABA

transporter is dependent on the presence of a leucine zipper motif in its second TM domain and the level of syntaxin expression [70, 71].

Inhibition of GABA transporters should inhibit the overexcitation observed during stroke and seizures by augmenting inhibition via classical GABA_A and GABA_B receptors. Thus, specific inhibitors of GABA transporters represent a new target class for the development of a novel therapeutic treatment for epilepsy. Similarly, compounds that stimulate the release of GABA by reversing GAT activity might also act as anticonvulsant and neuroprotective agents. The GAT1 inhibitors *cis*-3-aminocyclohexanecarboxylate, CI-966 (1-[2-[bis 4-(trifluoromethyl) phenyl]-methoxy] ethyl]-1,2,5,6-tetrahydro-3-pyridine carboxylic acid), nipecotic acid, NNC 05-711 (1-[2-[[[diphenylmethylene]amino]oxy]ethyl]-1,2,5,6-tetrahydro-3-pyridinecarboxylic acid), SK&F 89976-A (N-[4,4-diphenyl-3-butenyl]-3-piperidinecarboxylic acid), and tiagabine (Gabitril; (R)-1-[4,4-bis(3-methyl-2-thienyl)-3-butenyl]-3-piperidinecarboxylic acid]) attenuate the convulsive activity in animal models of epilepsy [33, 42, 72]. The rank order of potency of these compounds is NNC 05-711 > tiagabine > SK&F 89976-A > CI-966 [73]. Tiagabine is also efficient in the treatment of complex and refractory myoclonic seizures [72]. Some selective inhibitors of GAT2 and GAT3 are represented by β -alanine, hypotaurine, NNC 05-2045 and NNC 05-2090 [42, 74, 75]. These agents also display anticonvulsive properties [33, 42, 76], consistent with prediction.

12.2 GABA_A, GABA_B, AND GABA_C RECEPTORS

GABA acts via three classes of receptors (GABA_A, GABA_B, and GABA_C) in the vertebrate CNS that differ in their structure, function, and pharmacology. The vast majority of fast GABA responses that are inhibited by bicuculline and picrotoxin and enhanced by benzodiazepines or barbiturates result from the direct activation of an anion channel [4, 5, 9, 77–79] referred to as the GABA_A receptor [80].

A second type of ionotropic GABA receptor (GABA_C) is insensitive to bicuculline, benzodiazepines, and barbiturates [2, 81] (for a review see [82]). While GABA_A receptors are widely distributed in the CNS, the presence of GABA_C receptors is largely restricted to retinal bipolar or horizontal cells across vertebrate species [83–86]. GABA_A receptors are heterooligomeric channel-forming proteins, formed by different subunits that can belong to eight distinct classes (α , β , γ , δ , ϵ , π , θ , and ρ), providing the potential for a huge number of receptor subtypes (Fig. 12.1). In contrast, GABA_C receptors are homooligomeric receptors composed of ρ subunits [103–105]. Although the GABA_C receptor terminology is still used frequently, these receptors are thought to be part of the GABA_A receptor family [87].

Fast-responding GABA receptors are members of the Cys loop ligand-gated ion channel superfamily (reviewed in [87, 106, 107]) comprising nicotinic acetylcholine, GABA_A, GABA_C, glycine, and 5-HT₃ (5-hydroxytryptamine type 3) receptors that possess a characteristic loop formed by a disulfide bond between two cysteine residues. GABA binding to the extracellular domain of GABA_A and GABA_C receptors triggers the opening of an intrinsic chloride-selective ionophore that drives the membrane potential toward the reversal potential for Cl[−] ions (about −80 mV) in neurons. As a consequence, the probability that action potentials will be generated by excitatory neurotransmission is decreased. But GABA_A receptor activation can

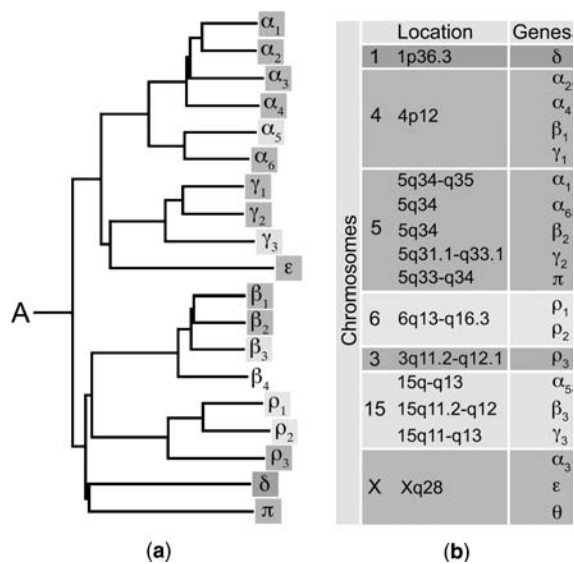

Figure 12.1 (a) Dendrogram depicting relation of amino acid sequences among GABA_A receptor subunits (adapted from [87]) and ancestral gene (A). (b) Localization of genes coding for GABA_A receptor within human genome (from [16–18, 88–102]). (See color insert.)

also induce depolarizing responses, particularly in embryonic neurons. This phenomenon is due to increased intracellular Cl[−] concentration in certain neurons that occurs prior to the expression of the KCC2 (potassium chloride co-transporter type 2) transporter, which is principally responsible for Cl[−] extrusion [108–113]. In adult brain, the GABA_A receptor can also mediate depolarizing responses under certain physiological and pathological conditions that involve intense receptor activation [114].

The slow response to GABA is mediated by GABA_B receptors (for a review see [115]), originally differentiated from GABA_A receptors on the basis of their sensitivity to activation by baclofen (β-parachlorophenyl GABA) [115]. Baclofen is used clinically as a spasmolytic [116, 117], mimicking the agonist effect of GABA in a stereoselective manner. The activation of GABA_B receptors by GABA inhibits neurotransmitter release from different tissue preparations and this effect is not blocked by bicuculline. GABA_B receptors are coupled to Ca²⁺ and K⁺ channels and to adenylyl cyclase via G proteins.

12.3 GABA_A RECEPTOR SUBUNIT TYPES

Twenty related GABA_A receptor subunit genes have been identified in the vertebrate nervous system thus far: 6α, 4β, 3γ, 1δ, 1ε, 1π, 1θ, and 3ρ [87, 101, 118]. A putative β₄-subunit gene, originally identified in chicken [119], has also been described in humans [120]. Figure 12.1 illustrates the seven different subunit sequence families of GABA_A and GABA_C receptors.

Alternative splicing of certain genes produces additional diversity of subunit sequence. There are two splice forms of β₂, β₄, and γ₂ subunits [119, 121–123] that

differ by the presence or absence of a short peptide in the long intracellular loop between TM3 and TM4. Splicing of exon 1 results in two alternative forms of the β_3 subunit [124]. The α_6 subunit is alternatively spliced in approximately 20% of its transcripts in rat brain, causing a deletion at the N-terminus of 10 amino acid residues of uncertain physiological significance [125].

GABA_A receptor subunits are up to 460 amino acids in length and composed of a large N-terminal extracellular domain four TM domains and a large intracellular loop between TM3 and TM4 [126] (Fig. 12.2). The N-terminal extracellular domain carries several potential sites for N-linked glycosylation [127] and two conserved cysteine residues. Binding sites for agonists and ligands of the benzodiazepine binding site are located at the interface between homologous parts of this domain that belong to different subunits. Binding sites for anesthetics, barbiturates, ethanol,

Figure 12.2 Schematic view of GABA_A receptor subunit. The N-terminal part is implicated in receptor assembly and formation of agonist and allosteric modulator binding sites. Different loops of the N-terminal domain are involved in formation of either agonist or benzodiazepine binding sites and signal transduction from ligand binding sites to the channel gate. The intracellular loop between TM1 and TM2 is forming the ion-selectivity filter. The TM2 domains of each subunit line up the channel pore. The loop between TM3 and TM4 is implicated in receptor regulation by secondary-messenger systems, trafficking, and clustering at synaptic membrane.

furosemide, and zinc are located within TM domains. Each subunit contributes to form the channel that is largely formed by residues of TM2 and possibly of TM3 [128–130].

12.4 REGIONAL DISTRIBUTION OF GABA_A RECEPTOR SUBUNITS IN CNS

Subunit isoform distribution in the brain has been studied by *in situ* hybridization [101, 102, 131–135] and immunohistochemical experiments [118, 136–148]. The individual subunits exhibit a distinct but overlapping regional and cellular distribution. The α_1 , β_1 , β_2 , β_3 , and γ_2 subunits are distributed with minor differences throughout the whole brain [148–150], whereas α_2 , α_3 , α_4 , α_5 , α_6 , γ_1 , and δ subunits are more confined to certain brain areas [147, 148].

The α_1 subunit is the most abundant and widely distributed in the brain. It exhibits lesser expression in the striatum, reticular thalamic nucleus, and internal granular layer of the olfactory bulb [146]. The second most abundant subunit is α_2 , which is preferentially located in forebrain areas [146, 148]. The highest α_2 immunoreactivity is observed in the olfactory bulb, striatum, nucleus accumbens, septum, dentate gyrus, amygdala, and hypothalamus and α_2 is less expressed in the thalamus (except reticular nucleus), midbrain, and brain stem areas. Colocalization of α_1 and α_2 with β_2 - and β_3 -subunit immunoreactivities is observed in most hypothalamic areas, raising the possibility of a preferential formation of $\alpha_{1/2}\beta_{2/3}$ receptors [141].

The α_3 subunit is strongly expressed in the glomerular and external plexiform layers of the olfactory bulb, the inner layers of the cerebral cortex, the reticular thalamic nucleus, and the zonal and superficial layers of the superior colliculus, the amygdala, and cranial nerve nuclei [146]. In the raphe nuclei the vast majority of serotonergic neurons express a strong α_3 -subunit immunoreactivity but they are devoid of α_1 -subunit staining and only a small population of serotonergic neurons coexpress both subunits [151, 152], although expression patterns of subunits overlap in certain brain regions. In the medial septum–diagonal band of Broca complex about 85% of neurons containing choline acetyltransferase express the α_3 but not the α_1 subunit. In contrast, 45–60% of parvalbumin-immunoreactive GABAergic neurons express both α_1 and α_3 subunits in various subnuclei of the medial septum–diagonal band of Broca complex, whereas most of the remaining parvalbumin positive neurons have intensive α_1 -subunit immunoreactivity [151, 152]. The α_3 subunit, however, is associated not only with serotonergic or cholinergic neurons but also with noradrenergic and dopaminergic neurons in the brain stem [151, 152]. These data indicate that serotonergic and GABAergic neurons express different α subunits, suggesting that they possess distinct subtypes of GABA_A receptors. The α_4 subunit is strongly expressed in the thalamus, dentate gyrus, olfactory tubercle, and basal ganglia [153]. The α_5 -subunit immunoreactivity is strongest in Ammon's horn, the olfactory bulb, and the hypothalamus [146]. The most striking example of subunit localization is illustrated by the α_6 subunit, which is exclusively expressed in granule cells of the cerebellum and the cochlear nucleus [146]. Colocalization of α_1 - and α_6 -subunit messenger ribonucleic acids (mRNAs) is found in about 50% of granule cells while 25% of these cells contain either the α_1 or α_6 subunit exclusively [154].

The β_2 subunit is perhaps the most widely distributed β subunit in the CNS whereas β_1 and β_3 subunits are less abundant [149]. The relative distribution for β_1 is hippocampus > cortex > cerebellum; for β_2 it is cerebellum > cortex > hippocampus [155, 156]. The β_1 subunit is also located in the neostriatum and inferior olive [146]. The ventral lateral geniculate nucleus contains β_1 , β_2 , and β_3 subunits as well as α_2 , α_3 , and γ_2 subunits [135, 146]. Strong diffusely located staining for the β_3 subunit is observed in the striatum, nucleus accumbens, and olfactory tubercle. The β_3 subunit is presumably colocalized with α_2 , α_4 , and δ subunits on dendrites of the medium spiny neurons. The β_2 subunit is mostly restricted to interneurons of these areas [147].

With regard to γ subunits, γ_2 is the most widely distributed throughout the CNS, whereas γ_1 and γ_3 are relatively scarce [150, 157]. The γ_1 subunit is the least abundant and is specifically distributed in the nervous system. The highest levels of γ_1 immunoreactivity are observed in the globus pallidus, ventral pallidum, entopeduncular nucleus, and substantia nigra pars reticulata, areas innervated by the striatum [146]. The γ_1 subunit is also found in the central and medial amygdaloid nuclei and the inferior olive [147]. The γ_3 subunit is expressed in most brain areas with low abundance, and the highest levels of γ_3 immunoreactivity are in substantia nigra pars compacta and the ventral tegmental area located on numerous presumptive dopaminergic neurons [147, 152].

The δ subunit displays strong but diffuse staining in the striatum, nucleus accumbens, and olfactory tubercle, where it is presumably colocalized with α_2 , α_4 , and β_3 subunits on dendrites of medium spiny neurons [147]. The δ subunit is colocalized with the α_4 subunit in the thalamus, striatum, outer layers of the cortex, dentate molecular layer, and in neonatal hippocampus [158–161] and with the α_6 subunit in the cerebellum [146]. In the neostriatum the δ subunit is colocalized with α_2 , α_4 , β_1 , and β_3 subunits [146].

In situ hybridization studies indicate that the ϵ -subunit is predominantly expressed by neurons located in septal and preoptic areas, various hypothalamic nuclei, amygdala, and thalamus [118, 144, 145]. The ϵ -subunit mRNA is detected in areas containing cholinergic (basal nucleus), dopaminergic (substantia nigra compacta), serotonergic (raphe nuclei), and noradrenergic (locus ceruleus) neurons [118, 144, 145].

The θ subunit [101] seems to be expressed in hypothalamus, amygdala, hippocampus, substantia nigra, dorsal raphe, and locus ceruleus [102, 144]. The θ subunits show overlapping expression patterns with ϵ subunits throughout the brain, especially in the septum, preoptic areas, various hypothalamic nuclei, amygdala, and thalamus, as well as in monoaminergic groups of neurons [144]. In this regard, in situ hybridization and immunohistochemical studies indicate that α_3 , θ , and ϵ subunits present an overlapping distribution in neurons of the dorsal raphe and the locus ceruleus, but θ mRNA is not detected in cholinergic cell groups [144]. These data are consistent with the notion that novel GABA_A receptor subunits may regulate neuroendocrine and modulatory systems in the CNS [118, 144].

The π subunit is detected in several peripheral human tissues as well as in the brain (hippocampus and temporal cortex) and is particularly abundant in the uterus [94]. The detailed regional distribution of the π subunit is unknown. The π subunit can coassemble with α , β , and γ subunits and confer unique ligand and electrophysiological properties to the resulting receptors [94, 162].

The ρ subunits seem to be preferentially expressed in the retina. Immunohistochemical studies of the retina reveal a staining pattern restricted to the terminals of bipolar cells in the inner plexiform layer that does not overlap with α - or β -subunit staining [163–166]. However, ρ -subunit mRNA is also present in the superior colliculus, dorsal lateral geniculate nucleus, and cerebral Purkinje cells [86, 168]. In addition, bicuculline-resistant and baclofen-independent effects of GABA occur in cerebellum [89, 169], superior colliculus [170, 171], amygdala [172], hippocampus [161, 173, 174], dorsal geniculate cells [175], and spinal cord [176]. This indicates that ρ subunits may be present in many regions of the CNS and are more prevalent than initially suspected.

12.5 SUBCELLULAR DISTRIBUTION OF GABA_A RECEPTORS

GABA_A receptors are widely distributed at inhibitory synapses on dendrites and neuronal cell bodies but they are also found at presynaptic, perisynaptic, and extrasynaptic sites (Fig. 12.3). To ask whether receptors occupying different locations have different functions, it is necessary to explore the subcellular distribution of

Figure 12.3 Schematic representation of GABAergic synapse. Concentration of GABA in the synaptic cleft is regulated by release, diffusion, and uptake mechanisms. Quantally released GABA can escape from synaptic cleft (GABA spillover) and potentially reach receptors located on extrasynaptic membranes, neighboring presynaptic terminals, and neighboring synapses. Transmitter spillover is thought to underlie both slow-rising GABA_A receptor-mediated IPSCs and part of the tonic GABA_A currents. GABA can also be released via a nonvesicular mechanism by neurons and glia. Once released, GABA can reach target receptors on presynaptic terminals, axon, and somatodendritic compartments. Several action potential-independent mechanisms have been proposed to mediate amino acid neurotransmitter release like reversed transport, stretch-activated anion channels, and P₂X₇ receptor-triggered release. However, blockade of the GABA transporter GAT-1 has no effect on the tonic current, whereas blockade of GAT-3 increases the current. Additional experimental verification of these nonvesicular release hypotheses suggested that GABA might in fact be released from either Golgi cell terminals or astrocytes through a nonvesicular Ca²⁺ independent mechanism. (See color insert.)

different GABA_A receptor subunits. Whereas immunohistochemical studies indicate that the majority of GABA_A receptors at the postsynaptic membrane are composed of α , β , and γ subunits [137–139, 157, 177–182], individual subunits exhibit a cell-specific subcellular distribution [181, 183–187]. For instance, cerebellar granule cells express α_1 , α_6 , β_2 , β_3 , γ_2 , and δ subunits that can form four to six distinct GABA_A receptor subtypes.

The α_1 , α_6 , β_2 , β_3 , and γ_2 subunits are mainly located in GABAergic Golgi synapses and only a small proportion is present at extrasynaptic sites. In contrast, δ subunits are present exclusively in extrasynaptic dendritic and somatic membranes [186]. Receptors composed of $\alpha_6\beta_X\delta$ subunits exhibit a 50-fold higher affinity for GABA than $\alpha_1\beta_X\gamma_2$ receptors [188, 189]. In addition, δ -containing receptors exhibit a smaller single-channel conductance and a much longer open time and do not desensitize after the prolonged presence of GABA as compared with $\alpha_1\beta_X\gamma_2$ receptors [189–191]. The kinetic characteristics and the exclusive extrasynaptic localization of $\alpha_6\beta_X\delta$ receptors suggest that these receptors mediate tonic inhibition in cerebellar granule cells [186, 191–195]. Phasic inhibition of granule cells is due to the transient activation of synaptic $\alpha_6\beta_X\gamma_2$ and/or $\alpha_1\beta_X\gamma_2$ receptors [186, 187, 189, 194].

There are two GABA_A receptor populations in CA1 pyramidal cells—synaptic and extrasynaptic receptors. Synaptic receptors generate rapid spontaneous inhibitory currents (IPSCs). In contrast, extrasynaptic receptors, which are predominant in excised patch preparations, mediate slow responses to brief GABA applications [194, 196, 197]. Receptors composed of $\alpha_4\beta_X\delta$ subunits exhibit properties similar to $\alpha_6\beta_X\delta$ receptors [198] and can, at least partially, be responsible for extrasynaptic tonic inhibition in these cells [195, 199]. Receptors composed of $\alpha_5\beta_X\gamma_2$ subunits are found at extrasynaptic sites in the hippocampus, probably mediating tonic inhibition [200]. The role of these extrasynaptically located GABA_A receptors mediating tonic inhibition in cerebellar granule cells alter the gain of transmission of rate-coded sensory information. Tonic inhibition can be modulated pharmacologically by changes in GABA release and uptake and GABA_A receptor modulators such as ethanol and neurosteroids [189, 197, 201, 202].

Although GABA_A receptors are mainly located in the postsynaptic membrane, presynaptic inhibition appears to be mediated by these receptors as reported in early work based upon pharmacological analysis [203–205], which was confirmed and extended using modern techniques [206–210]. Activation of presynaptic GABA_A receptors at axo-axonic synapses induces depolarization and inhibition of neurotransmitter release. The precise mechanism by which depolarization mediated by presynaptic GABA_A receptors affects transmitter release is not known; however, two main hypotheses have been proposed [211]. First, depolarization can affect transmitter release by acting on other ion channels at or very close to the release site. Thus, depolarization-induced inactivation of voltage-gated Na^+ and/or Ca^{2+} channels leads to a reduction in the amplitude of action potentials and a decrease of Ca^{2+} influx, reducing the probability of neurotransmitter exocytosis. Moreover, depolarization can decrease the driving force for Ca^{2+} influx immediately after the action potential, contributing to the reduction in exocytosis [212]. Second, activation of GABA_A receptors located at a distance from the release sites interfere with the propagation of the action potential into the presynaptic terminal by causing a decrease in membrane resistivity [213, 214]. Although primarily based on computer

simulations, this shunting hypothesis has been supported by experimental evidence from large unmyelinated axons in crayfish [215].

Subunit composition of presynaptic GABA_A receptors in symmetric synapses is generally similar to that of postsynaptic receptors [216]. GABA_A receptors in symmetric synapses are distributed along the entire postsynaptic membrane, whereas in asymmetric synapses the receptors are clustered at the edge of the presynaptic specialization. Thus in the inhibitory synapses GABA_A receptors are localized precisely opposite the GABA release sites of synaptic boutons, whereas in excitatory synapses they are located close to but excluded from the central active zone [216]. At presynaptic inhibitory boutons of crayfish neuromuscular junction, which represents another type of asymmetric synapse, GABA_A autoreceptors are composed of at least the α_3 and $\beta_{2/3}$ subunits [217].

Collectively the results indicate that the interaction of GABA with the receptive target neuron occurs at focal synaptic, perisynaptic, and extrasynaptic sites and that the number and subunit subtype composition of GABA_A receptors present in different populations of synapses may have profound influences on the characteristics of neurotransmission [218–220].

12.6 GABA_A RECEPTOR STRUCTURE

GABA_A receptor subunits share amino acid sequence similarity with nicotinic acetylcholine receptor (nAChR) subunits. Electron optical diffraction of the muscle nAChR receptor in *Torpedo* electric organ (a specialized tissue with exceptionally high receptor density) shows that its three-dimensional structure is that of a pentamer, with the ion channel located in the center of a rosette of five membrane-spanning protein subunits [221–224]. Structural analyses of GABA_A receptors are more complex since no such rich receptor sources exist. Electron microscopic image analysis of GABA_A receptors purified from pig brain cortex indicates a pentameric structure with a central pore [225].

Figure 12.4 Schematic representation of $\alpha\beta\gamma$ GABA_A receptor in postsynaptic membrane. (See color insert.)

Several lines of evidence support a pentameric structure for the GABA_A receptor. Hydrodynamic estimates of the size of GABA_A receptors in solution, either native [226] or $\alpha_1\beta_3\gamma_2$ recombinant receptors [227], are consistent with the molecular weight of a pentamer. Furthermore, the integral ratios of the subunits combined in several forms of functional recombinant receptors, as determined by diverse methods, fit best in each case with total of five subunits [227–231]. Analysis of receptors formed by linked subunits also indicates a pentameric stoichiometry [229, 232, 233] (Fig. 12.4).

Whereas estimates suggest that more than 151,887 GABA_A pentameric receptor subtypes with distinct subunit composition can be formed, at least theoretically [234], some neurons express appreciable quantities of only 2 or 3 different types of subunits and not all subunits can assemble efficiently [107].

12.7 HOMO-OLIGOMERIC GABA_A RECEPTORS

Recombinant expression studies indicate that some of the GABA_A receptor subunits can form homo-oligomers with efficiencies of assembly that vary depending upon the subunit subtype. Homo-oligomeric GABA_A receptors composed of ρ subunits are highly expressed [95, 103–105, 235, 236] while homo-oligomeric receptors containing murine β_1 or β_3 and human γ_{2L} subunits exhibit lower expression levels [237–241].

Interestingly, channels formed by murine or rat β_1 [239, 242] or β_3 subunits [240] can open spontaneously in the absence of GABA and openings are inhibited by the channel blocker picrotoxin. This effect is a function of species since it is not observed with human or bovine β_1 subunits [239, 243, 244].

12.8 HETERO-OLIGOMERIC GABA_A RECEPTORS

12.8.1 Composed of Two Different Subunit Subtypes

Different $\alpha\beta$ -subunit combinations are expressed efficiently and form GABA-activated channels in all systems investigated [245–248]. In contrast, the assembly efficiency of receptors containing $\alpha\gamma$ or $\beta\gamma$ ($\alpha_1\gamma_2$ or $\beta_3\gamma_2$) subunits in HEK-293 cells is low [227]. Receptors composed of $\beta_1\gamma_{2S}$, $\beta_2\gamma_{2S}$ and $\beta_3\gamma_{2S}$ subunits are formed in HEK-293 cells with an efficiency similar to that of homo-oligomeric β_{1-3} receptors, but with different pharmacological properties [249, 250]. The subunit combinations $\alpha_1\gamma_2$ or $\beta_2\gamma_{2L}$ are retained within the endoplasmatic reticulum (ER) [237, 238] and seem unlikely to be functional receptors. These subunit combinations might be formed under certain experimental conditions, such as in the presence of suitable chaperone proteins or at high subunit concentrations. The cotransfection of $\alpha_1\epsilon$ -, $\beta_1\epsilon$ -, $\alpha_1\pi$ -, or $\beta_1\pi$ -subunit combinations does not result in the expression of functional channels in HEK cells [94, 251]. It is unknown whether $\alpha\delta$, $\beta\delta$, or $\gamma\delta$ subunits can form GABA_A receptors.

The ρ subunit can form a functional receptor in vivo [252]. The ρ subunits can also assemble with γ_2 subunits and possibly with glycine receptor subunits to form functional receptors in the retina [253–255].

12.8.2 Composed of Three or More Different Subunit Subtypes

Most GABA_A receptors are composed of α , β , and γ subunits [106, 107, 256]. These subunits can form receptors comprising $(2\alpha/2\beta/\gamma)$, $(2\alpha/\beta/2\gamma)$, or $(\alpha/2\beta/2\gamma)$ assuming a pentameric structure. The most abundant GABA_A receptor in adult mammalian brain is of the $\alpha_1\beta_2\gamma_2$ subtype [106, 107] (Fig. 12.5).

The existence of three identical subunits in the same receptor molecule, for example, $(3\alpha/\beta/\gamma)$, $(\alpha/3\beta/\gamma)$, and $(\alpha/\beta/3\gamma)$ receptors, is not supported by immunoprecipitation [227], electrophysiological [228, 230], and fluorescence energy transfer [231] studies.

Receptors containing two different α - or β -subunit isoforms can assemble and exhibit properties distinct from those receptors containing a single subunit isoform [245, 246, 257–263]. Receptors composed of α_1 , β_1 , the long splice variant of γ_2 , and δ ($\alpha_1\beta_1\gamma_{2L}\delta$) or α_1 , β_3 , γ_3 , and π ($\alpha_1\beta_3\pi$ and $\alpha_1\beta_3\gamma_3\pi$) subunits can also be formed and exhibit properties distinct from $\alpha_1\beta_1\gamma_{2L}$ or $\alpha_1\beta_1\delta$ receptors [190, 261, 264] and from $\alpha_1\beta_3$ or $\alpha_1\beta_3\gamma_3$ receptors [265].

Although experiments investigating the expression of five different subunits have been performed in *Xenopus* oocytes, the results obtained were difficult to interpret [246]. This is not surprising because a variety of different receptor subtypes composed of three, four, or five different subunits could have been formed from five different subunits coexpressed in an oocyte, and all could have contributed to the chloride current measured in these cells. This problem could be addressed by linking multi-subunits using gene fusion, as has already been applied successfully to GABA_A receptors [232, 233, 263, 266].

12.9 GABA_A RECEPTOR ASSEMBLY

GABA_A receptor assembly occurs within the ER [267–270]. Distinct subunit subtypes may confer functionality such as sensitivity to modulation by endogenous ligands such as neurosteroids [271–274], second-messenger systems [270, 275], subcellular localization [237], or long-term differences in the regulation of surface expression [237, 238]. Many neurons express multiple receptor subunit mRNAs [107, 133], suggesting the presence of cellular mechanisms for differential receptor assembly.

The correct arrangement of subunits around the pore depends on assembly constraints conferred by the interfaces of neighboring subunits (Fig. 12.5). The presence of multiple assembly signals in the same subunit can lead to a differential interaction with other subunits and can permit the construction of different GABA_A receptors. Individual subunits are not committed to a particular receptor subtype but can function as universal building blocks in the generation of diverse receptor compositions [107].

Residues 54–68 in the (–) interface of the α_1 are important for the assembly with β subunits [279–281]. Residues 80–100 in the (+) interface of the α_1 subunit are important for the assembly with the γ_2 subunit [282]. Residue Q67 [279] is relevant for the assembly of α_1 with β_3 but not with γ_2 subunits. Conversion of a single amino acid in α_1 to that of γ_2 (R66A) is sufficient to alter the assembly profile of the α_1 subunit to that of the γ_2 subunit. The amino acid R66 is required for the assembly of

Figure 12.5 Top view of GABA_A receptor. (a) Each subunit contacts two other subunits at two different subunit interfaces. In the homologous nAChR these interfaces have been called principal and complementing [276, 277]. In AChBP the nomenclature “+” and “−” has also been used to denominate these interfaces [278]. (b) Top view of TM part of GABA_A receptor, TM2s of all five subunits contribute to Cl^- channel. (See color insert.)

$\alpha_1\beta_2$ but not $\alpha_1\beta_1$ or $\alpha_1\beta_3$ [283, 284], and two tryptophan residues $\alpha_1\text{W69}$ and $\alpha_1\text{W94}$ are critical for the assembly of the GABA_A receptor pentamer [285].

In the (−) interface of β_2 and β_3 subunits the amino acids 52–66 are critical for the assembly with α_1 subunits [249, 280, 281]. The residues 76–89 located in the (+) interface of the β_3 subunit are important for the assembly with α_1 subunit [286].

The amino acid sequences $\gamma_2\text{67–81}$ [280] and $\gamma_3\text{70–84}$ [287] located in the (−) interface and $\gamma_2\text{83–90}$ and $\gamma_2\text{91–104}$ located in the (+) interface [281] are involved in the assembly of α_1 and β_3 subunits. The amino acid $\gamma_2\text{W82}$ residing in the (−) interface is critical for assembly with α_1 and β_2 subunits [288]. Interestingly, the assembly signals in the α , β , and γ subunits [287, 327, 328] overlap with the GABA [289] and benzodiazepine binding sites [288, 290–294], which are formed at subunit interfaces between the α/β and α/γ subunits, respectively.

12.10 TRAFFICKING OF GABA_A RECEPTORS

Receptor trafficking is a rather complicated process that differs depending on cell type and the subunit composition of receptors [295, 296]. Different proteins that interact with GABA_A receptor subunits are believed to regulate the trafficking of receptors to specific subcellular locations (Fig. 12.6).

The clustering of GABA_A receptors at postsynaptic membranes depends on the scaffolding protein gephyrin, but no evidence for an action of gephyrin in trafficking could be found as of this writing. Studies in gephyrin knockout (KO) mice indicate that GABA_A receptors containing α_2 and γ_2 subunits require gephyrin for synaptic targeting [302] and γ_2 subunit KO mice exhibit a loss in synaptic gephyrin immunoreactivity [303] and postsynaptic GABA_A receptors [304]. These results demonstrate that the presence of γ_2 subunits and gephyrin is important for postsynaptic receptor clustering.

Figure 12.6 GABA_A receptor trafficking to membrane is facilitated by many receptor-associated proteins. GABA_A receptors are assembled in the endoplasmic reticulum. Subsequently competent subunit combinations (e.g. $\alpha\beta$ and $\alpha\beta\gamma$) are transported to the Golgi. In this organelle, assembled GABA_A receptors interact with proteins that facilitate transport to neuronal membrane. The GABA_A receptor γ_2 subunit can interact with GABARAP [314], a protein that interacts with and stabilizes the GABA_A receptor in neuronal membrane and catalytically inactive phospholipase P130 [317] that is able to compete with GABARAP for the same binding site on the γ_2 subunit. Additionally they interact with NSF, a protein that plays a key role in intracellular transport. These multiple protein–protein interactions are believed to facilitate GABA_A receptor intracellular transport. GABA_A receptors also interact directly with the ubiquitin-like protein Plic-1 [307], which stabilizes intracellular receptor pools from the secretory or endocytic pathway that can be recycled and inserted back into membrane. In addition, GABA_A receptors at synaptic sites undergo constitutive dynaminddependent, clathrin-mediated endocytosis. This process is mediated by the interaction of receptor β and γ subunits with α and β adaptins, proteins that are essential for the receptor internalization into clathrin-coated pits. Internalized receptors enter the endosomal transport system, from which they can be returned to the cell surface or degraded. At synaptic sites, GABA_A receptors colocalize with gephyrin, which is believed to play a crucial role in receptor clustering at synapses. In addition to their roles in the secretory pathway, GABARAP, P130, and Plic-1 may also function in the endocytic pathway to mediate and regulate GABA_A receptor trafficking and stability of intracellular receptor pools. GABA_A receptors at cell surface are also intimately associated with several other receptors and signaling proteins, including the functional GABA_B receptor [297], dopamine D₅ [298], ATP-gated excitatory P₂X receptor [299–301], RACK-1, and the β II isoform of PKC [268]. (See color insert.)

Although the results suggest a role for gephyrin in GABA_A receptor clustering, a direct interaction between these two proteins has not been demonstrated. In addition, the postsynaptic localization of α_1 and α_5 subunits in the spinal cord of gephyrin in KO mice is unaffected [305]. Taken together, these observations have stimulated the search for additional proteins important for GABA_A receptor clustering [306–308].

The first protein identified was the GABA_A receptor-associated protein (GABARAP), a 17-kDa polypeptide that interacts specifically with the major intracellular domains of receptor γ_2 subunits [308, 309]. GABARAP is a member of a protein family, which includes the light chain 3 (LC3) of microtubule-associated proteins 1A and 1B, the Golgi-associated adenosine triphosphatase (ATPase) enhancer (GATE-16), and the yeast ortholog Apg8p/Aut7p. Interestingly, GATE-16, LC3, and Apg8p/Aut7p all participate in membrane-trafficking processes [310–312]. Structurally, GABARAP is comprised of an amino-terminal tubulin binding region, which is important for tubulin polymerization, and an ubiquitin-like carboxy-terminal domain, which is capable of binding to the intracellular loop of γ_2 subunit [309, 313].

Overexpression of GABARAP in a mammalian cell line results in increased numbers of clustered GABA_A receptors with modified kinetics [3314]. However, GABARAP immunoreactivity is low in GABAergic synapses and is predominantly localized to intracellular membranes, including the edges of Golgi stacks and a sub synaptic tubulovesicular compartment [315]. Furthermore, GABARAP interacts in intracellular membrane compartments with the *N*-ethylmaleimide-sensitive factor (NSF), a protein involved in membrane fusion events [315]. Expression of recombinant GABARAP cDNA in cultured neurons induces an increase in GABA_A receptor levels at the plasma membrane. These results support a role for GABARAP in the intracellular transport and cell surface targeting of receptors [316].

Yeast two-hybrid screening indicates that GABARAP interacts with p130, a protein structurally related to phospholipase C but lacking the catalytic activity [317]. In addition, GABARAP binding to the GABA_A receptor γ_2 subunit is competitively inhibited by p130. These results, together with the intracellular localization of p130, suggest a role of p130 controlling the membrane transport and assembly of functional GABA_A receptors [317].

Inhibitory neurotransmission can be regulated by the insertion of newly synthesized or recycled GABA_A receptors into synaptic membrane. There is a direct relationship between the number of synaptic GABA_A receptors and the strength of the synapse [318, 319] so modulation of the insertion and/or removal rate of GABA_A receptors into or from the synaptic membrane has a marked effect on the amplitude of mIPSCs (miniature inhibitory postsynaptic currents) [268].

Insulin induces a rapid recruitment of functional GABA_A receptors to postsynaptic plasma membranes, thereby increasing the amplitude of the GABA_A receptor-mediated mIPSCs [320]. In contrast, brain-derived neurotrophic factor (BDNF) produces a reduction of mIPSCs by decreasing the number of postsynaptic GABA_A receptors in cultured hippocampal neurons [321].

The ubiquitin-like protein Plic-1 interacts with the major intracellular loop of the GABA_A receptor α and β subunits and increases the half-life of intracellular receptor pools [307]. Plic-1 has a molecular weight of 67 kDa and contains a ubiquitin-like amino terminus and a carboxy-terminal ubiquitin-associated domain. The Plic-1 immunoreactivity GABA_A receptor is associated with cisternae, the Golgi compartment, invaginations of the plasma membrane, and structures in the vicinity of the postsynaptic membrane [307]. These results indicate that Plic-1 increases the number of GABA_A receptors available for insertion into the plasma membrane [307].

Palmitoylation of cysteine residues is a reversible posttranslational modification that regulates the trafficking and function of different membrane proteins in neurons (for a review see [322–324]). The Golgi-specific zinc finger protein (GODZ) is a palmitoyltransferase that interacts with cysteines in the large cytoplasmic loop of γ_{1-3} GABA_A receptor subunits [325]. Rathenberg et al. [324] demonstrated that the γ_2 subunit is palmitoylated. Reduction of palmitoylation by specific inhibitors, or mutations introduced in the palmitoylation sites of the γ_2 subunit decrease receptor clustering, suggesting that palmitoylation may regulate of GABA_A receptor function of inhibitory synapses.

Several lines of evidence indicate that GABA_A receptors are internalized via clathrin-mediated endocytosis. These include the presence of GABA_A receptors in clathrin-coated vesicles [326, 327] and the interaction of GABA_A receptors with the clathrin adapter protein 2 (AP2) complex, which is critical for membrane protein endocytosis [267, 328]. Furthermore, the β_2 subunit has a dileucine AP2 adaptin binding motif that is important for receptor internalization [329, 330].

12.11 MODULATION OF GABA_A RECEPTORS BY PHOSPHORYLATION

The intracellular domains of GABA_A receptor subunits can be phosphorylated by a variety of kinases at serine, threonine, and tyrosine residues [331] (Fig. 12.7). Studies on recombinant GABA_A receptors have revealed that the major intracellular loops of receptor β and γ subunits can be phosphorylated by a variety of protein kinases, namely cyclic adenosine mono-phosphate (cAMP)-dependent protein kinase (PKA) [275, 336–344], protein kinase C (PKC) [336, 338, 345–349], the tyrosine kinase Src (sarcoma) [335, 350, 351], tyrosine kinase receptor B (TrkB) [352–354], Ca^{2+} /Calmodulin type II-dependent protein kinase (CamKII) [355, 356], and cyclic guanine mono-phosphate (cGMP)-dependent protein kinase [338, 355, 356].

Modulation of GABA_A receptor function by PKA phosphorylation depends on the β -subunit subtype. GABA-mediated currents are inhibited by phosphorylation of Ser409 in the β_1 subunit by PKA; however, phosphorylation of Ser408 and Ser409 in the β_3 subunit(s) by PKA potentiates the GABA response. Activation of PKA does not alter responses from β_2 subunit-containing receptors [349, 356, 357].

PKC phosphorylates the conserved serine residues β_1 S409 and β_2 S410 [336, 348, 349], as does CamKII [348] and cGMP-dependent protein kinase [356]. CamKII phosphorylates residue β_3 Ser383 [356].

The γ subunits are phosphorylated by PKC at residues γ_{2L} S327/ γ_{2S} S327 and γ_{2L} S343 [121, 338, 346]; by CamKII at residues γ_{2L} S327, γ_{2L} S343, and γ_{2L} T348 [355]; and by the prototypic tyrosine kinase Src at residues γ_2 Y365 and γ_2 Y367 [350, 351, 359, 360].

Phosphorylation of GABA_A receptor $\beta_{1/2}$ and $\gamma_{2S/L}$ subunits by PKC inhibits receptor function [361]. Activation of PKC in HEK-293 cells expressing recombinant GABA_A-Rs also induces a reduction in the number of receptors at the cell surface, but the mechanism is independent of receptor phosphorylation [362].

Different signaling pathways control phosphorylation of GABA_A receptors in neurons. The receptor for activated C kinase (RACK-1) and PKC bind independently to adjacent residues in the intracellular domain of the β_1 subunit. Inhibition of RACK-1 binding to β_1 decreases the PKC-mediated phosphorylation of the residue

Figure 12.7 GABA_A receptors are intimately linked to G-protein-coupled receptors (GPCRs) via multiple protein kinases and scaffold proteins. GABA_A receptor β and γ_2 subunits are phosphorylated by PKA and PKC upon the activation of corresponding GPCRs for muscarinic M1 [359], dopamine D4 [332], and serotonin 5-HT₂ [333, 334] and 5-HT₄ [268, 335]. Phosphorylation of GABA_A receptor β_1 and β_3 subunits by PKA is dependent upon AKAP150/79, which directly interacts with these receptor subunits and able to bind PKA that is composed of regulatory (R) and catalytic (C) subunits in both active and inactive form. In addition, the GABA_A receptor β_{1-3} and γ_2 -subunits can be phosphorylated by PKC. Upon activation of the appropriate GPCR, PKC-mediated phosphorylation is facilitated through the direct (but independent) interaction of the RACK-1 [358], the β isoform of PKC with the GABA_A receptor β_{1-3} subunits. RACK-1 regulates the function of GABA_A receptors via control of activity of PKC associated with these proteins. The GABA_A receptor γ_2 subunit is also phosphorylated by Src kinase [331], which is also able to bind to the β subunits. Finally, depending on subunit composition of particular GABA_A receptor, phosphorylation can modulate its function in the direction of both inhibition and potentiation. (See color insert.)

β_1 S404 and the inhibitory effect of PKC on GABA-evoked currents [359]. Activation of muscarinic acetylcholine receptors (AChRs) inhibited GABA_A receptor function by a PKC-mediated pathway that depends on the binding of RACK-1 to the GABA_A receptor. These results indicate that phosphorylation of GABA_A receptors by PKC and the regulation of receptor function by PKC-mediated signaling pathways depend on RACK-1 binding to receptors [359]. RACK-1 also participates in the PKC-dependent modulation of GABA_A receptor currents by 5-HT₂ receptors in cortical neurons [363].

A kinase anchoring proteins (AKAPs) often target PKA to its substrates [364]. The neuronal AKAP (AKAP79/150) binds to GABA_A receptors containing the β_1 or β_3 but not the α_1 , α_2 , α_3 , α_6 , β_2 , γ_2 , or δ subunits and is critical for PKA-dependent phosphorylation of the highly conserved β_1 S409/ β_3 S408 residues [365]. These results suggest a mechanism for the PKA-mediated phosphorylation of GABA_A receptor subtypes. Electrophysiological evidence also additionally suggested another AKAP, the scaffold protein Yotiao [366], which may be involved in PKA-mediated modulation of GABA_A receptor function [332].

Activation of tyrosine kinase receptors B (TrkB) by BDNF produces a biphasic temporal modulation of GABA_A receptor function in cultured hippocampal neurons. Early exposure to neurotrophin (5 min after BDNF application) enhances GABA-mediated currents while a late exposure (30 min after BDNF application) inhibits GABA-evoked responses. This modulation parallels an initial increase in PKC-mediated phosphorylation of GABA_A receptors and a subsequent receptor dephosphorylation by the protein phosphatase 2A (PP2A). These results indicate that BDNF dynamically regulates GABA_A receptor function by changing the phosphorylation state of receptors. The mechanism seems to involve a differential recruitment of PKC, RACK-1, and PP2A to GABA_A receptors [353]. The modulation of GABA_A receptor responses by BDNF is age dependent since BDNF potentiates GABA-gated currents of pyramidal neurons isolated from postnatal day 6 rats and inhibits GABA responses on postnatal day 14 [352].

12.12 GABA_A RECEPTOR PHARMACOLOGY

Distinct GABA_A receptor subtypes differ in their channel kinetics, affinity for GABA, rate of desensitization, subcellular positioning, and pharmacology. In the absence of pharmacological tools to specifically and selectively distinguish subunit subtypes, the function *in vivo* of defined receptor subtypes cannot be fully investigated. Therefore, alternative approaches have been employed to address this problem. For instance, specific subunit isoforms can be genetically deleted by creating KO mice, and although such deletions are expected to affect all receptors containing the particular subunit subtype, compensatory upregulation of other subunit subtypes occurs. The knockin approach, wherein a subunit subtype is mutated in order to alter its pharmacological properties, is an alternative strategy that in principle reduces these compensatory changes. Thus, for the α_1 , α_2 , α_3 , and α_5 subunits, replacing histidine-101 with arginine (α_1 H101R, α_2 H101R, α_3 H101R, and α_5 H101R) renders GABA_A receptors insensitive to classical benzodiazepines [367, 368]. A similar approach has been applied to β_2 and β_3 subunits with the introduction of β_2 N265S and β_3 N265S mutations, which render receptors insensitive to general anesthetics [369, 370].

12.13 PHARMACOLOGY OF GABA_A RECEPTORS CONTAINING DIFFERENT α SUBUNITS: SEARCH FOR MOLECULAR BASIS OF ANXIETY AND HYPNOSIS

12.13.1 Terminology

Experts in the field use two different terminologies to describe the effects of benzodiazepine and related therapeutic agents on GABA_A receptor function and on the pharmacodynamic effects of the drugs under investigation. The action of the neurotransmitter GABA (the natural agonist) is blocked by compounds (antagonists; such as bicuculline) that reduce its binding to the GABA recognition site. Benzodiazepines (such as chlordiazepoxide and diazepam) and related chemical entities are known to potentiate the response of GABA_A receptors by shifting the dose–effect

curve for GABA to the left, and this potentiation of the response to the agonist is referred to as positive modulation [11–15, 371–373], and such compounds are positive modulators. Positive modulators almost always shift the dose–effect curve to the left, increasing the potency of GABA for its receptor, but in principle the term would apply to compounds that might increase the maximum response (or efficacy) of GABA. Negative modulators such as β -carboline shift the dose–effect curve for GABA to the right and can also decrease the maximal response (efficacy) to GABA. Null modulators such as flumazenil exhibit little or no modulation of the GABA response but antagonize the binding and action of both positive and negative modulators.

When positive modulators are administered to animals, they exert various pharmacological effects (including sedation, hypnosis, muscle relaxation, and amnesic and anxiolytic activity) and thus can be referred to as behavioral agonists. However, the term agonist should not be used to describe the modulatory actions of these compounds on the GABA_A receptor. Negative modulators are referred to as inverse agonists when administered *in vivo* as they exhibit physiological effects that are generally the inverse of positive modulators, eliciting anxiogenic responses and some even enhancing learning and memory. Null modulators exhibit little or no physiological effects in experimental animals or human subjects but block the effects of positive modulators such as benzodiazepine agonists and negative modulators such as β -carboline inverse agonists.

12.13.2 Determining Selectivity of Modulators

In an attempt to develop an anxiolytic therapeutic agent, an intensive discovery effort was directed toward the design of subtype selective benzodiazepine recognition site ligands. Zolpidem, one such compound, was for a long time considered to be GABA_{A1} receptor selective and has been used in a number of animal studies as standard for the contribution of α_1 -containing receptors to functional responses *in vivo* and *in vitro* systems. However, zolpidem's selectivity *in vivo* has not been established. The strongest evidence for selectivity is based on radioligand binding studies in which it exhibits only a 3.7- to 5.9-fold higher affinity toward $\alpha_1\beta_2\gamma_2$ -containing versus $\alpha_2\beta_2\gamma_2$ -containing receptors, although it does exhibit a much greater separation of affinities with other α -subunit-containing receptor subtypes (see Tables 12.1 and 12.2). There is a fundamental difference between preference and selectivity—a compound is generally considered to be selective for a certain subunit subtype if it exhibits a ≥ 10 -fold higher affinity with respect to the other subtypes. There is insufficient information from functional determinations to come to general conclusions with regard to zolpidem potency, but zaleplon and zopiclone exhibit 2- to 4-fold preference for α_1 - over α_2 -subunit-containing GABA_A receptors (Table 12.2).

12.13.3 α_1 Subunit

The behavioral effects of zolpidem, a GABA_{A1}-preferring positive modulator of GABA action with higher affinity toward $\alpha_1\beta_2\gamma_2$ versus $\alpha_2\beta_2\gamma_2$ receptors, and triazolam, a nonselective positive modulator, were studied in Squirrel monkeys. Flumazenil, which is a nonselective weak partial-positive modulator of GABA action (antagonist of benzodiazepine binding), antagonizes the behavioral effects of both zolpidem and triazolam. This suggests that both zolpidem and triazolam are acting

through the classical benzodiazepine recognition site *in vivo*. The GABA_{A1}-preferring negative modulator of GABA action β -CCt (β -carboline-3-carboxylate-*t*-butyl ester) behaviorally reverses the ataxic effects produced by zolpidem and triazolam. These data have been interpreted to indicate that antagonism at GABA_{A1} receptors is responsible for the observed behavior and that these receptors mediate ataxic effects of benzodiazepines [374].

The above pharmacological evidence could also be explained by effects of β -CCt exerted through GABA_{A1} receptors compensating for ataxic effects of zolpidem and triazolam exerted through any one of the many other GABA_A receptor subtypes these drugs interact with at pharmacologically active doses.

The α_1 -subunit KO mice develop normally and do not exhibit alterations in locomotor activity or measures of mouse anxiety levels. KO of this subunit induces and may thus be compensated for by overexpression of α_2 and α_3 subunits, which are evidently sufficient to sustain GABAergic inhibition [167, 375–377]. This deletion of α_1 is accompanied by the development of GABA-induced currents with slower decay kinetics as compared with wild-type responses in cerebellar neurons [378]. The α_1 -subunit KO mice also exhibit an increased sensitivity to the locomotor-stimulating actions of ethanol and a reduced hypnotic effect of some anesthetics [379].

In the α_1 -subunit KO mouse, diazepam continues to exhibit an effect characterized as anxiolysis using the elevated plus-maze test as a measure of mouse anxiety. These KO mice are insensitive to the anticonvulsant effect of diazepam. The hypnotic effect of a high dose of zolpidem is reduced by 66% in the KO mice as measured by the duration of the loss of the righting reflex while the effect of a high dose of diazepam is increased by 57% in these animals [375, 376].

In mice carrying the α_1 H101R mutation diazepam loses its ability to induce sedation [380–384]. In addition, the anterograde amnesic and anticonvulsant actions of diazepam are reduced in α_1 knockin mice, suggesting that these effects are mediated by α_1 -containing receptors [380, 381]. Collectively, the results in α_1 -subunit KO mice have been interpreted to indicate that this subunit is not required for the anxiolytic effects of nonselective benzodiazepines in rodents. In very recent studies, however, the role of α_1 -subunit-containing receptors in anxiolysis has been challenged as one of the compounds, ocinaplon, which have comparable affinity to α_1 - and α_2 -subunit-containing receptors displayed robust anxiolysis without sedative side effects [385]. The pharmacological effects of benzodiazepine site negative modulators or inverse agonists are opposite to those of benzodiazepine site positive modulators or agonists. However, Ro 15-4513, a benzodiazepine site inverse agonist, displays some agonistic actions in α_1 H101R knockin mice. Thus, in wild-type animals Ro 15-4513 increases locomotion and exerts proconvulsant effects whereas in α_1 H101R knockin mice this inverse agonist inhibits locomotion and is anticonvulsant. These data indicate that at least some of the pharmacological actions of benzodiazepine site inverse agonists are mediated by α_1 -subunit-containing GABA_A receptors [381].

12.13.4 α_2 Subunit

Diazepam does not act as an anxiolytic in mice carrying the α_2 H101R point mutation while it remains anxiolytic in α_1 H101R, α_3 H126R, and α_5 H105R knockin mice [383]. Importantly, this lack of response to the anxiolytic actions of benzodiazepine modulatory site ligands is specific since in α_2 H101R mice the anxiolytic effects of

sodium pentobarbital persist. Thus, it has been proposed that the anxiolytic action of diazepam is selectively mediated by α_2 -containing GABA_A receptors [383].

However, ocinaplon effectively potentiates GABA responses of α_1 -containing ($\alpha_1\beta_2\gamma_2$) receptors and is a selective anxiolytic drug with little sedative activity in humans and experimental animals, indicating that the pharmacological reality in rat, nonhuman primate, and human may be more complex than originally thought based on research in KO mice [385]. The results with ocinaplon strongly suggest that the sedative side effects of benzodiazepine positive modulators are not mediated, at least in a simple way, by potentiation of α_1 -containing receptors as suggested previously from results obtained using knockin mice [380–384].

12.13.5 α_3 Subunit

A novel 3-heteroaryl-5,6-bis(aryl)-1-methyl-2-pyridone that acts as a negative modulator (inverse agonist) selective for α_3 -containing receptors is proconvulsant and anxiogenic in rats [386]. At very high doses, diazepam loses its myorelaxant effects in the α_3 H126R knockin mice as compared with wild-type animals, suggesting that this pharmacological effect can be influenced by GABA_A receptors containing α_3 subunits [387]. The thalamic reticular nucleus that expresses only α_3 -containing GABA_A receptor regulates thalamocortical oscillations. The suppression of thalamic oscillations by clonazepam observed in slices of wild-type and α_1 H101R mice is absent in α_3 H126R mutant mice, indicating that this effect may be mediated by α_3 -containing GABA_A receptors [388].

12.13.6 α_4 Subunit

Steroid withdrawal paradigms in rats constitute models of premenstrual, postpartum, and postmenopausal syndromes and are accompanied by enhanced anxiety and susceptibility to seizures and an increase in α_4 -subunit levels. These effects are prevented by the suppression of α_4 -subunit expression, suggesting, that the upregulation of α_4 -containing GABA_A receptors leads to an increase in anxiety and neuronal excitability [389–393].

12.13.7 α_5 Subunit

The contribution of α_5 -containing receptors was studied in vivo using compound L-655,708, a partial negative allosteric modulator that exhibits at least 50-fold selectivity for α_5 -containing receptors over those containing α_1 , α_2 , α_3 , α_5 , and α_6 subunits. Elevated plus-maze performance was used to assess for the anxiolytic effects of L-655,708 (0.625–5 mg/kg i.p.) in male mice. Mice treated with L-655,708 showed a marked increase in the frequency of entries and time spent in closed arms and a decreased frequency of entries and time spent in open arms as compared with the control group. These observations suggest that L-655,708 produces an anxiogenic effect that influences elevated plus-maze performance. These observations highlight the importance of GABA_A receptors containing an α_5 subunit, which is expressed in the hippocampus, a region of the brain which has been implicated along with the amygdala in the modulation of anxiety states [394].

Two transgenic models have been generated to study the contribution of α_5 subunit. In one the entire subunit has been deleted [395], and in the second the α_5 H105R point mutation has been introduced [396]. Apart from an incomplete muscle-relaxing effect, neither the sedative, anticonvulsant, nor anxiolytic effects of diazepam were reduced in α_5 H105R mice.

Both of these genetically modified mice showed an improved performance in animal models of spatial learning and memory [395, 396], whereas performances on non-hippocampal-dependent learning and on anxiety tasks were similar to those of the wild-type control animals. These data suggest that α_5 -containing GABA_A receptors play a key role in cognitive processes by controlling a component of synaptic transmission in the CA1 region of the hippocampus and selective inhibitors of α_5 -subunit-containing receptors could have use as cognitive enhancers, for instance in mild cognitive impaired elderly or Alzheimer's disease patients [395].

12.13.8 α_6 Subunit

Studies on KO mice that lack the α_6 subunit reported no change in the response of these mice to pentobarbital, general anesthetics, or ethanol compared with wild-type mice [397], but the KO were more sensitive to the motor-impairing actions of diazepam than their wild-type counterparts [398], but not to development of tolerance to motor-impairing actions [399]. Studies of motor performance (rotarod, horizontal-wire, pole-descending, staircase, and swimming tests) reveal no differences in baseline functioning or learning among α_6 -deficient and wild-type mice. However, rotarod performance of the KO mice is significantly more impaired by diazepam (5–20 mg/kg, i.p.) when compared with wild-type mice. Ethanol (2.0–2.5 g/kg, i.p.) produces a similar impairment in α_6 -deficient and wild-type mice. Diazepam-induced ataxia in α_6 -deficient mice could be reversed by the benzodiazepine site antagonist flumazenil, indicating involvement of other GABA_A receptors. These findings suggest that GABA_A receptor α_6 -subunit-dependent actions can be compensated for by other receptor subunits, but the α_6 -subunit plays an important role in modulation of the ataxic side effects of benzodiazepines [398].

In addition, a selective posttranslational loss of the δ subunit was apparent in cerebellar granule cells, which indicates that the δ subunit is coassembled with the α_6 subunit [146]. The absence of the α_6 subunit triggered various additional changes in the cerebellum, which included a reduction in the affinity of the GABA_A receptor for muscimol [397], an increase in the number of receptors containing the β_3 subunit compared with wild type [424], and, interestingly, a compensatory upregulation of a K⁺ channel (TASK-1) in granule cells [400].

12.14 PHARMACOLOGY OF GABA_A RECEPTORS CONTAINING DIFFERENT β SUBUNITS

There are numerous observations that describe altered expression of β subunits in patients with temporal lobe epilepsy [401–403] and also in various experimental models of epilepsy [404, 405]. Deletion of the gene encoding the β_3 subunit results in mice that possess only half of the normal density of GABA_A receptors in the brain [406]. Most of these mice die in the neonatal period; however, a few survive and

grow to normal body size [407], although these mice display various neurological impairments, including hyperresponsiveness to sensory stimuli [408], strong motor impairment, and epileptic seizures [409], which might be due to the lack of β_3 -containing receptors as “desynchronizers” of neuronal activity [410, 411].

The sedative and anesthetic effects of anesthetics may also be mediated by GABA_A receptors containing different β -subunit isoforms [412–414]. Mice lacking the β_3 subunit exhibit an attenuated sedative/hypnotic response to midazolam and etomidate but respond normally to the effects of pentobarbital, enflurane, and halothane, suggesting that these agents act at different GABA_A receptor subunits [412]. Studies of sleep time comparing mice lacking the β_3 subunit with wild-type mice reveal a small but significant reduction in rapid eye movement (REM) sleep time in β_3 KO mice. Baseline electroencephalographic (EEG) delta power is significantly greater in KO mice than in wild-type mice. Although midazolam decreases non-REM sleep delta power of EEG and REM sleep time in wild-type mice, only the former response is seen in the KO mice. These results suggest that although the β_3 subunit is not the molecular site of action of midazolam, it may be involved in regulating its effects on REM sleep [415].

Studies of etomidate-insensitive mice carrying β_2 N265S mutation showed that these animals were lacking the sedative effects to subanesthetic dosages of etomidate (0.3–7.5 mg/kg). This suggests that the sedative effects produced by the etomidate are mediated by the β_2 subunit [369]. Loss of the pedal withdrawal reflex and suppression of wave amplitude in the electroencephalogram were observed in mice with an etomidate-insensitive β_2 subunit following exposure to high dosages (10–15 mg/kg) of etomidate, suggesting that the β_3 subunit is somehow involved in the modulation of anesthetic effects and loss of consciousness [369]. Furthermore, KO mice spent less time sleeping and recovered faster from the effects of etomidate than did wild-type mice, providing additional support for the conclusion that the sedative/hypnotic effects of etomidate are mediated primarily via β_2 subunits and that compounds selective for receptors containing β_3 subunits may be able to provide anesthesia with improved recovery time [369]. The latter hypothesis was confirmed in the study of knockin mice carrying the β_3 N265S mutation that rendered mice insensitive to the anesthetics propofol and etomidate. Moreover, it was observed that the potency of volatile anesthetics (enflurane and halothane) on these receptors is reduced, suggesting that it has a key role in mediating the hypnotic and immobilizing responses in vivo. However, actions of volatile anesthetics were not completely abolished and appear to involve a broader spectrum of molecular targets, for example, GABA_A receptors containing β_1 and β_2 subunits [370].

12.15 PHARMACOLOGY OF GABA_A RECEPTORS CONTAINING DIFFERENT γ SUBUNITS

In mice with a targeted disruption of the γ_2 gene diazepam fails to induce sedation and to impair the righting reflex. Furthermore, electrophysiological experiments performed in dorsal root ganglion cells indicate a lack of potentiation of GABA responses by flunitrazepam. These results are consistent with a loss of 94% of benzodiazepine binding sites in neonatal brains of γ_2 -subunit-deficient mice [416].

Most homozygous γ_2 KO mice die perinatally, and this might be due to the reduction in channel conductance that is observed in these animals and the requirement of the γ_2 subunit for synaptic clustering of GABA_A receptors [303]. Mice heterozygous for the γ_2 subunit KO mutation develop and behave normally and the synaptic clustering of GABA_A receptors is only partly reduced. These animals show a high-anxiety response to natural and learned aversive stimuli as well as a cognitive bias for threat cues [417].

In mice lacking the long splice variant of the γ_2 subunit (γ_{2L}) the sleep time after midazolam and zolpidem administration is increased compared to wild-type mice. In contrast, responses to etomidate and pentobarbital are unchanged. Although the number of GABA_A receptors was not altered in γ_{2L} KO mice, there was a corresponding increase in the affinity of brain membranes for positive modulators (midazolam, diazepam, and zolpidem), while the affinity for negative modulators (β -CCM and Ro 15-4513) was decreased. These findings suggest that absence of the long splice variant of the γ_2 subunit increases the affinity of positive modulators for GABA_A receptors that is translated into a modest increase in behavioral sensitivity to these compounds [418]. Electrophysiological studies of human GABA_A receptors expressed in *Xenopus* oocytes indicate that the modulatory effect of neurosteroids depends on the γ -subunit isoform. Receptors composed of γ_2 subunits are more sensitive to the neurosteroid 5 α -pregnan-3 α -ol-20-one compared to γ_1 -containing receptors [419].

12.16 PHARMACOLOGY OF GABA_A RECEPTORS CONTAINING δ SUBUNITS

Disruption of the gene encoding the δ subunit produces mice with a higher susceptibility to pentylenetetrazole-induced seizures [420], and this genetic deletion is accompanied by an increase in γ_2 - and a decrease in α_4 -subunit expressions [421, 422]. These KO mice display a reduction in sleep time following the administration of the neurosteroids alphaxalone and pregnanolone, whereas the response to pentobarbital, propofol, etomidate, ketamine, and midazolam is indistinguishable from that observed in wild-type mice [423].

Electrophysiological studies with recombinant GABA_A receptors expressed in heterologous expression systems indicate that the presence of δ subunits increases the sensitivity of GABA_A receptors to the stimulatory effects of neurosteroids [272, 419]. The sensitivity of GABA-evoked currents to pregnanolone sulfate, a negative allosteric modulator of GABA_A receptors, is increased in the ventral basal complex of the thalamus in δ -subunit-deficient mice. However, in the same brain region of KO mice the effect of 3 α ,5 α -tetrahydrodeoxycorticosterone, a positive allosteric modulator, is similar to wild-type mice. These data suggest that positive and negative neurosteroid modulators of GABA_A receptors have different binding sites [424]. δ -Subunit deficiency also leads to alterations in the behavioral responses to ethanol. Thus, δ KO mice present a decreased ethanol consumption, reduced withdrawal effects after chronic ethanol administration, and decreased anticonvulsant response to ethanol. However, the anxiolytic and hypothermic effects of ethanol are unaffected [425].

12.17 PHARMACOLOGY OF GABA_A RECEPTORS CONTAINING “RARE” SUBUNITS

Pharmacological properties of GABA_A receptors containing the ϵ , θ , and π subunits have not yet been studied in detail. The ϵ -subunit expression is restricted to the hypothalamus and hippocampus, suggesting a specific role regulating inhibitory neurotransmission [251]. Electrophysiological experiments using recombinant receptors indicate that expression of the ϵ subunit in combination with α and β subunits renders spontaneously active GABA_A receptor channels that are insensitive to benzodiazepines [251]. There is a disagreement about the effect of allosteric modulators on ϵ -containing GABA_A receptors. Davies et al. [426] and Belelli et al. [419] have found that substitution of the ϵ for the γ subunit abolishes the effect of neurosteroids and pentobarbital. In contrast, results from Whiting et al. [251] and Neelands et al. [162] indicate that ϵ -containing receptors are modulated by these agents.

The θ subunit shares 50% of its amino acid sequence with the β subunits. The distribution of the θ subunit is restricted to monoaminergic neurons [101].

The π subunit is expressed in the hippocampus and in nonneuronal tissues such as the uterus [94]. The amino acid sequence of this subunit is similar to that of the β (37%), δ (35%), and ρ (33%), subunits [94, 162]. It can coassemble with either $\alpha_5\beta_3$ or $\alpha_5\beta_3\gamma_3$ subunits to produce recombinant GABA_A receptors that are less sensitive to diazepam. [162]. The role of θ and π subunits in the nervous system remains to be fully explored.

12.18 STRUCTURAL DETERMINANTS OF RECEPTOR ACTIVATION

GABA is the endogenous activator of GABA_A receptors. Different compounds with distinct intrinsic activities are also recognized by the agonist binding site of the GABA_A receptor. The binding of agonists (Fig. 12.8) (e.g., GABA or muscimol) is coupled to the opening of the channel, the so-called channel gating process. Partial agonists (e.g., THIP (4,5,6,7-tetrahydroisoxazolo[5,4-c]pyridin-3-ol), or isoguvacine) differ from agonists with regard to channel opening efficacy. The binding of a competitive antagonist [e.g., bicuculline or gabazine (SR-95531)] stabilizes the closed state of the receptor channel (Fig. 12.9). Competitive antagonists are viewed as classic competitive inhibitors of GABA_A receptor [427], but there are indications that they can induce conformational changes [428–430].

Molecular techniques have identified residues that may participate in binding and gating of GABA channels [128, 293, 429, 431–433]. Agonist binding appears to involve multiple, discontinuous protein domains, often from separate receptor subunits [293, 419, 424, 425]. Binding can thus involve a type of chelation, or “induced fit,” process [436–439] in which separate regions of the receptor come together to interact with the agonist. A chelation mechanism implies that the agonist may reciprocally organize separate regions of the receptor into a relatively rare conformation such as an open state. Such reciprocal interactions trap agonist in the binding site [430, 440] and can be related to the conformational change produced in the agonist binding site (Fig. 12.10).

Electron diffraction measurements on nAChR have revealed the structure of this Cys loop ligand-gated channel at up to 4.6 Å resolution [221–223, 441, 442]. The conformational change in the ligand binding domain (LBD) in nAChRs produced by

Figure 12.8 GABA_A receptor ligands: agonists (GABA, muscimol, isoguvacine) and partial agonists (THIP, P4S).

Figure 12.9 GABA_A receptor ligands: competitive antagonists.

Figure 12.10 Hypothetical model of GABA_A receptor gating proposed on the basis of EM cryomicroscopy experiments performed on another Cys loop receptor—the nicotinic acetylcholine receptor [314]. The agonist-induced rotations in the extracellular domain of subunits are transmitted to the gate via TM1, which is directly linked to the receptor extracellular domain and electrostatic interaction between loop 2 and 7 and TM2–TM3 linker. The rotations destabilize the gate, causing the TM2 helices of each subunit to adopt an alternative configuration, which is permeable to the chloride ions.

agonists primarily affects the α subunits (equivalent to β subunits in GABA_A receptors), rotating their inner (pore-facing) β sheets by 15 degrees about an axis passing through the disulfide bridge and oriented perpendicular to the membrane plane [441, 442].

Agonist binding rates are often slower than expected for a diffusion-limited process [438, 443–445], implying that an energy-requiring process precedes or

accompanies binding [438]. Under the agonist chelation hypothesis, this process would correspond to structural rearrangements in the binding site that lead to channel opening. Therefore, ligands capable of opening the channel must bind slower than the diffusion limit, whereas ligands that do not open the channel (i.e., competitive antagonists) bind more rapidly than agonists [439].

12.19 ARCHITECTURE OF AGONIST BINDING SITES

Residues implicated in agonist binding are located in at least six different non contiguous extracellular N-terminal regions of the α and β subunits. These regions have been designated as loops A–F in the homologous nAChR [276, 277]. The agonist binding site of GABA_A receptors is formed by the (–) side of α and the (+) side of β subunit (Fig. 12.5a) [288, 293, 446]. Residues in different loops are likely to have different functional roles. Some residues may directly contact the agonist, some may be important for maintaining the structural integrity of the binding site, and others may mediate local conformational movements within the site. GABA binding sites composed from different α - and β -subunit isoforms may have different GABA sensitivities [447]. Two agonist molecules bind to the GABA_A receptor. Even though the two agonist sites are located at similar interfaces formed by identical (–) sides of α and (+) sides of β subunits, they have dissimilar properties: Site 2 (flanked by α and γ subunits) has higher affinity for GABA than site 1 (flanked by γ and β subunits). In contrast, muscimol and bicuculline exhibit some selectivity for site 1 [266] (Fig. 12.5).

The following residues are thought to take part in the formation of the agonist site (see Fig. 12.11): on the α_1 subunit, residues F64 [431, 448], R66, and S68 [293] on loop D; K116, R119, and I120 [449–451] on loop E; and V178, V180, and D183 [452] on loop F. Complementary residues in the β_2 subunit include Y97 and L99 [453] on loop A; Y157 and T160 [444] on loop B, and T202, S204, Y205, R207, and S209 [429, 432] on loop C. Interestingly, domains involved in the formation of the GABA and benzodiazepine binding sites are homologous (reviewed in [292]).

The spatial arrangement of these residues was unclear until direct crystallographic data of a protein involved in synaptic transmission of the snail *Lymnaea stagnalis* were obtained. This water-soluble protein is called acetylcholine binding protein (AChBP). The AChBP subunit is 210 residues long, forms a stable homopentamer [278, 455], and shares 24% sequence homology with the N-terminal part of human α_7 nicotinic receptor subunit and about 15% with subunits of GABA_A receptor family and can be used for homology modeling [456].

12.20 TRANSDUCTION OF BINDING TO GATING

To achieve gating, rearrangements induced by binding of GABA within the LBD must be transmitted to the channel gate, located within the membrane. Such conformational changes during channel activation have been detected in the regions of the receptor located near TM1, in the TM2 segment [128, 434], and in the TM2–TM3 loop [435]. The extracellular part of subunits forming the LBD is mechanically coupled with the transmembrane part at TM1, a part of the subunit where the pre-TM1 β sheet (β' 10) becomes the TM1 α helix and enters the membrane [536]. Inspection of the

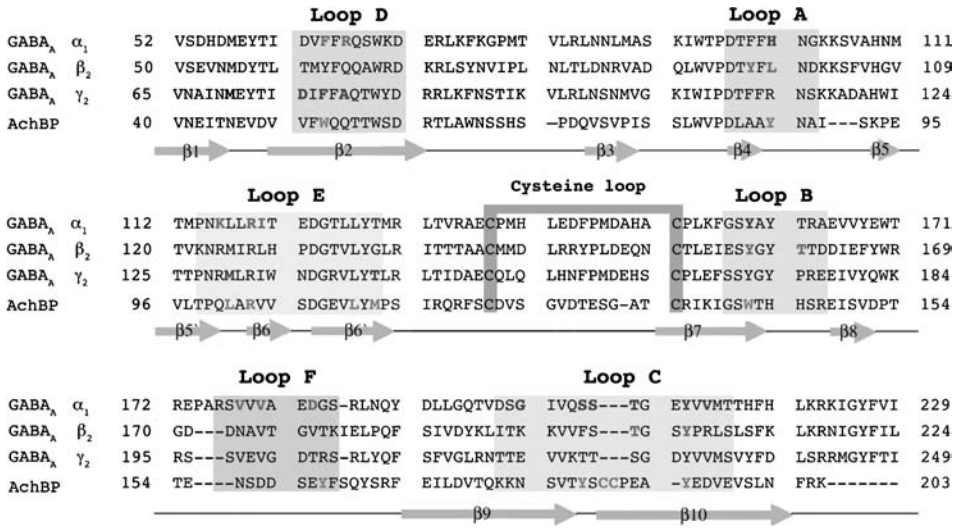

Figure 12.11 Alignment of the ligand binding domain of the GABA_A receptor α₁, β₂ and γ₂ subunits, and AChBP. Residues forming the cysteine loop are highlighted in grey. The colored boxes are six regions known in the six-loop agonist binding site model: loops A (green), B (pink), C (light brown), D (blue), E (cyan), F (light grey) [276, 277]. Residues, which are thought to form agonist binding sites, are in bold red, those implicated in the formation of benzodiazepine binding site are labeled in bold blue. Residues implicated in formation of benzodiazepine binding sites are homologous to residues forming agonist binding sites (reviewed in [294]). Residues within a radius of 5 Å of 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) molecules in AChBP structure also fall within these regions, with those from the plus and minus sides of the subunit located in loops A, B and C and D, E, and F, respectively [278]. They are highlighted in bold green. Precursor peptide sequences of rat subunits were obtained from the National Center for Biotechnology Information (NCBI) (access codes: P18504 for α₁; P15432 for β₂; P22723 for γ₂). Ligand binding domains were aligned to mature peptide sequence of α₁ subunit using MaxHom [744] at Predict Protein (<http://www.predictprotein.org/>). (See color insert.)

GABA_A subunit sequences shows that TM2–TM3 loops contain conserved lysine residues, which can assist in transduction of conformational change via electrostatic interactions between charge pairs formed by loop 2 and loop 7 with the TM2–TM3 linker [457] (see Fig. 12.12).

Residues implicating loop 2 of the LBD in the transduction of conformational changes are identified on both α and β subunits in homologous positions: α₁D57 [458] and β₂D56 [459]. The distribution of residues within loop 7 of α and β subunits is non equivalent, the α₁ subunit contain α₁D149 [458] and the β₂ subunit β₂D139, β₂D146 [459], which may imply a differential role of different subunits in receptor activation. This differential role of the β₂ subunit is stressed by residue β₂K215, which is located in the pre-TM1 segment [459].

Conventional mutagenesis identified a set of residues located on the TM2–TM2 linker which upon mutation strongly affect gating; these are α₁L263 [460], α₂R274 and α₂L277 [461], α₁L276 [462], α₁K279 [458, 463], β₂K274 [459, 463], β₂L259, and γ₂L274 [460]. Charge exchange mutations and sulfhydryl trapping experiments helped to identify residues on the TM2–TM3 linker corresponding to interaction

Figure 12.12 The TM2–TM3 loop is resolved in all subunits. The locations of the inner-sheet loop, loop 2 ($\beta 1/\beta 2$), and the loop 7 ($\beta 6'/\beta 7$) Cys loop disulfide bridge from the ligand binding domain are shown. In both subunits residues implicated in gating efficacy are shown as letters. In α subunit α_1 D56 in the $\beta 1/\beta 2$ loop and α_1 D149 form electrostatic interactions with α_1 K279 on TM2 and can be trapped in disulfide trapping experiment. The same is true for the β subunit, where β_2 K274 possibly interacts with β_2 D139 and pre-TM1 residue β_2 K215 interacts with β_2 D56, β_2 D139, and β_2 D146.

pairs on loop 2 and loop 7. Thus on α_1 , these interacting pairs of residues are α_1 D57 and α_1 K279 and α_1 D149 and α_1 K279. They seem to form electrostatic interactions and, as was shown in trapping experiments, they move closer to one another during gating and can be trapped with reducing agents [458]. With the aid of similar strategies, residues were found on the β_2 subunit implicated in the coupling of the LBD to the TM. These are β_2 D56, β_2 D139, and β_2 D146 that can be trapped together with residue β_2 K215 and to some lesser extent with β_2 K274 [459].

Results of Kash et al. [458, 459] suggest that there are pronounced differences in intradomain interactions of individual α and β subunits which may contribute to asymmetric propagation/distribution of conformational changes during receptor activation. The latter is supported by results obtained on homologous nAChRs during activation where binding of agonist produces 15 degrees of rotation within inner β sheets of the receptor α subunits (β in GABA_A receptors) [224, 441, 442]. Additionally, individual GABA sites display dissimilar binding properties [266]. This functional asymmetry that exists on the level of both individual receptor subunits and agonist binding sites implies asymmetrical propagation/induction of conformational changes within the receptor during activation.

The mutation of homologous residues on the γ_2 subunit (γ_2 S280 [289, 746] and γ_2 K289 [463]) located on γ_2 TM2–TM3 linker did not affect receptor gating by GABA. However, these residues located within the TM2–TM3 loop of α and γ subunits affect modulation of GABA_A receptor by benzodiazepines (see below).

12.21 THE CHANNEL PORE AND ITS ION SELECTIVITY

The channel pore is a complex symmetrical assembly of TM segments from all receptor subunits that achieves stability through productive interactions between TM segments. When the stabilizing contributions of the TM segments are perturbed sufficiently, cooperative changes can be set in motion causing the entire structure to

collapse toward an open state that allows free but selective passage of ions (Fig. 12.13).

The channel pore in all Cys loop receptors is made up from five TM2 segments, one from each subunit. Using the substituted-cysteine accessibility method 9 of 26 residues tested in the α subunit are identified as exposed to water [128]; on the β subunit the number of exposed residues is 15 of 26 tested [130].

The stability of the gate is maintained by leucine residues at the 9' turn of TM2 segment which are highly conserved among all Cys loop receptor subunits and are important for normal gating. Functional studies inferred a role for the 9' leucines (α_1 L264, β_2 L259, and γ_2 L278) in channel gating based on changes of the properties of the resting state of the receptor that produce spontaneous opening of the channel in the absence of agonist GABA [230, 460, 465–467]. Additionally, L253 was identified in β subunits and is located closer to the cytoplasmic end of the channel pore. Mutation of L253 produces receptors that are spontaneously active; that is, the open and closed states are in active equilibrium at comparable concentrations in the absence of agonist [468, 469].

The ion selectivity of all Cys loop receptors is determined by residues located at the TM1–TM2 linker; this ring of charges starts from the -1 position of TM2 according to the pore numbering system of Cys loop receptors [470–473]. Comparison of amino acid sequences of other anion channels indicates that this ring is conserved among all anion channels and formed by a proline, alanine, and arginine in the TM1–TM2 linker: α_1 P253 (β_1 P248), α_1 A254 (β_1 A249) and α_1 R255 (β_1 R250) ($-2'$ $-1'$, $0'$ respectively) [474].

The first study describing a conversion of the charge selectivity in homomeric GABA_A receptors composed of ρ subunits indicates that deletion of conserved proline at the $-2'$ turn and mutation of alanine at $-1'$ to glutamate can reverse conductance of these anionic channels [475, 476]. In heteromeric $\alpha\beta\gamma$ GABA_A receptors charge selectivity was first studied using the $\alpha_2\beta_3\gamma_2$ receptor isoform [477]. Amino acid residues in the TM1–TM2 linker of each of the three GABA_A receptor subunits were replaced by the corresponding acid residues from the nAChR

Figure 12.13 Schematic view of TM2 domain of the α and β subunits. Circles on α and β subunits filled with grey represent water-exposed residues facing the channel pore as detected by cysteine-reactive MTS (methanethiosulfonate) substances. Residues depicted on transmembrane helices are implicated in maintaining the normal properties of the gate; those shown on stretch of amino acids entering the membrane control the ion selectivity of the channel.

α_7 . Expression of a mutated β_3 subunit with wild-type α_2 and γ_2 subunits renders receptor channels that conduct cations [477]. No currents can be recorded from receptors with mutations in both the α_2 and β_3 subunits. These data indicate that the TM1–TM2 linkers of neither the α_2 nor the γ_2 subunits influence ion selectivity. Thus, ion selectivity of heteromeric $\alpha_2\beta_3\gamma_2$ GABA_A receptors is determined by β_3 subunits [477].

12.22 GABA_A RECEPTOR DESENSITIZATION AND DEACTIVATION

Virtually all ligand-gated ion channels have a set of intrinsic macroscopic properties describing their behavior in the presence of agonist; these are affinity, deactivation, and desensitization constants. Affinity is described by the sensitivity of a receptor for a given agonist. Deactivation is a characteristic delay between agonist removal and channel closing, while desensitization is the decrease in the ability of a receptor to open during the continuous presence of agonist. Desensitization is generally considered to be a negative-feedback mechanism that reduces the peak of IPSCs, but it has been suggested recently that desensitization may, in fact, enhance GABAergic transmission by prolonging IPSCs [478–480]. Jones and Westbrook [481] suggested that high-affinity, long-lived desensitized states delay unbinding of GABA from receptor, thus allowing additional late openings to occur before unbinding and slowing deactivation. Desensitization of GABA_A receptors can occur at fast (~ 10 ms), intermediate (~ 150 ms), and slow (~ 1500 ms) rates [481–484].

Additionally, receptors with specific desensitization and deactivation profiles may contribute to different types of inhibition, namely phasic and tonic. It has been observed that $\alpha\beta\gamma$ receptors containing the γ_{2L} subunit, which usually can be found at synapses, showed prominent fast desensitization accompanied by prolonged deactivation. In contrast, $\alpha\beta\delta$ receptors (with δ in place of the γ subunit) are located extrasynaptically, lack fast desensitization, and deactivate rapidly, despite having a fourfold higher affinity for GABA [484]. Thus, fast desensitization and slow deactivation might provide a mechanism that overcomes the consequences of exposing synaptic receptors to fast transients of high concentrations of neurotransmitter, whereas high-affinity, slow-desensitizing receptors are designed to sense low extrasynaptic GABA concentrations. Several studies on chimeric receptors indicate that residues located in TM1 and TM2 segments are involved in the modulation of desensitization in nACh, GABA_A, and 5-HT₃ receptors [229, 466, 485–489] (Fig. 12.14).

Studies of GABA_A receptor chimeras identify protein domains that control desensitization/deactivation kinetics. The control of desensitization and deactivation is more dependent on TM1 sequences (at least in α_1 , α_6 , γ_{2L} , δ , or ρ subunits) and less affected by the identity of TM2 segment [489–491]. Exchange mutants between the δ and γ_{2L} subunits identified two adjacent residues $\delta V233$ and $\delta Y234$ in the TM1 of the δ subunit as structural determinants of fast deactivation. Exchange of these residues to corresponding residues of the γ_{2L} subunit $\gamma_{2L}Y235$, $\gamma_{2L}F236$ confers prolonged deactivation without affecting the desensitization time course [491].

Mutation of residues α_1L264 , α_6T266 , and α_1S270 in TM2 segments, which are important for maintaining functional properties of the channel gate, increases the

Figure 12.14 Schematic view of TM2 and TM3 of GABA_A receptor subunit. Residues shown are identified as important for specific desensitization/deactivation properties of GABA_A receptors.

gating efficacy of GABA_A receptors by slowing channel closing rates and thus prolonging deactivation [229, 492].

12.23 MODULATION OF GABA_A RECEPTOR VIA ALLOSTERIC BINDING SITES: BENZODIAZEPINE RECOGNITION SITE

In 1957, Sternbach and his colleagues at Hoffmann-La Roche discovered by serendipity that a new compound, chlordiazepoxide, decreased muscle tension, reduced fear, and was anticonvulsant in animals. A few years later diazepam was discovered [493]. These compounds were the first clinically used benzodiazepines and their discovery ushered a new era in the treatment of anxiety and related disorders [493–495].

Since the 1960s benzodiazepines have become the primary pharmacological treatment for generalized anxiety disorder, epilepsy, sleep disorders, and alcohol withdrawal and in the induction and maintenance of anesthesia [495–503]. By the mid-1970s researchers worldwide started to acknowledge a possible involvement of GABAergic systems in the action of benzodiazepines [504, 505]. Finally, by the end of the 1970s the involvement of GABA_A receptors in the action of benzodiazepines became firmly established by a number of laboratories worldwide (Figs. 12.15 and 12.11–14, 506) [11–14, 506]. The number of compounds with the benzodiazepine template has been reported to exceed 3000. Among the pharmacological agents that allosterically modulate GABA_A receptors, the benzodiazepines have gained major clinical relevance [495, 497, 498, 500].

Ligands of the benzodiazepine recognition site have been subdivided into three classes according to their intrinsic activity: positive allosteric modulators, negative allosteric modulators, and null modulators (Figs. 12.17–19). The terms “agonist,” “inverse agonist,” and “antagonist” are also used for these compounds when referring specifically to actions at the benzodiazepine recognition site. The term agonist should, however, properly be reserved for reference to GABA, which is the natural agonist at the GABA_A receptor, and the term antagonist (e.g., bicuculline) should be reserved for those compounds that block GABA agonism. Agonism and inverse agonism could properly be used when referring to the pharmacological effects of these compounds in vivo.

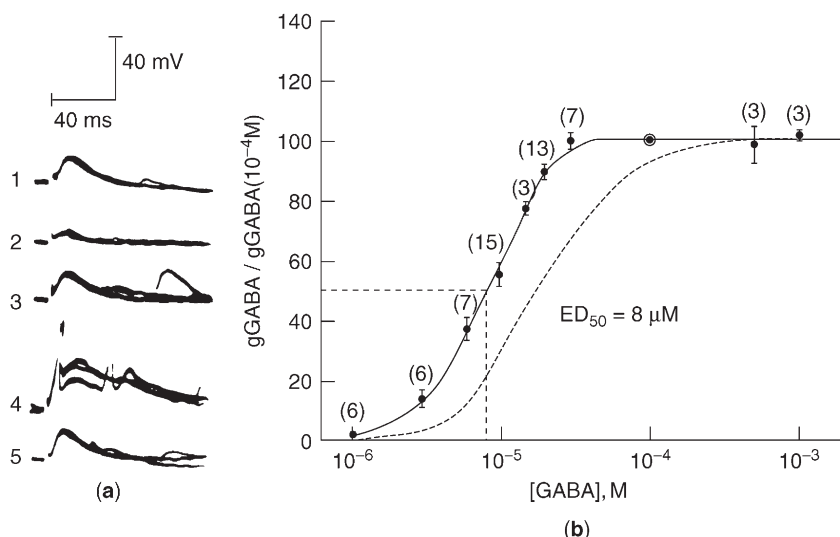

Figure 12.15 (a) Chlordiazepoxide (CDPX) potentiates stimulus-evoked, bicuculline-sensitive IPSPs. Superimposed oscilloscope traces show evoked synaptic potentials recorded with a potassium chloride electrode from the same chick spinal cord neuron. Records labeled 1–5 were obtained in sequence: 1, control; 2, during pressure injection of 100 μM bicuculline; 3, 1 min later (return to control); 4, during injection of 120 μM CDPX; 5, 2 min later. The break in each trace immediately before the evoked response is the stimulus artifact. Spontaneous synaptic potentials appear late in records. Resting potential was -80 mV. (b) Effect of CDPX on the GABA dose–response function on chick spinal cord neurons. The response to each test dose of GABA on a neuron was expressed as a fraction of the response of the same neuron to a 0.1 mM standard dose. The solid line represents the GABA response measured in the presence of 100 μM CDPX in the bath. Bars represent standard error (SE); the number of cells tested at each concentration is given in parentheses on the curve. The dashed line is a plot of the GABA dose–response function determined in the absence of CDPX (8). This curve has been normalized to the same maximum as the first curve. [These figures are reproduced from [11] (*Nature London*) and [13] (*Journal of Neurophysiology*) with permission.]

Positive allosteric modulators such as classical benzodiazepines bind to GABA_A receptors and induce a conformational change [129] increasing the affinity of binding sites for GABA without affecting the maximum GABA response. At the single-receptor level these conformational changes result in an increased probability of channel opening or gating [509]. Antagonists of the benzodiazepine site do not affect GABA-elicited responses. However, they prevent other allosteric modulators from binding and thus from allosteric modulation of receptor function. Negative allosteric modulators have opposite effects to positive allosteric modulators, decreasing affinity for GABA.

The use of classical benzodiazepines is often associated with side effects. The sedative effects associated with benzodiazepines can impair an individual to operate a machinery and thus those individuals whose livelihood depends on their ability to operate heavy equipment such as a bulldozer or forklift may not be willing or able to take the medication while at work without jeopardizing their job.

Sedation is not the only side effect: Daytime drowsiness with long-acting compounds which may even accumulate in the body with multiple use or rebound

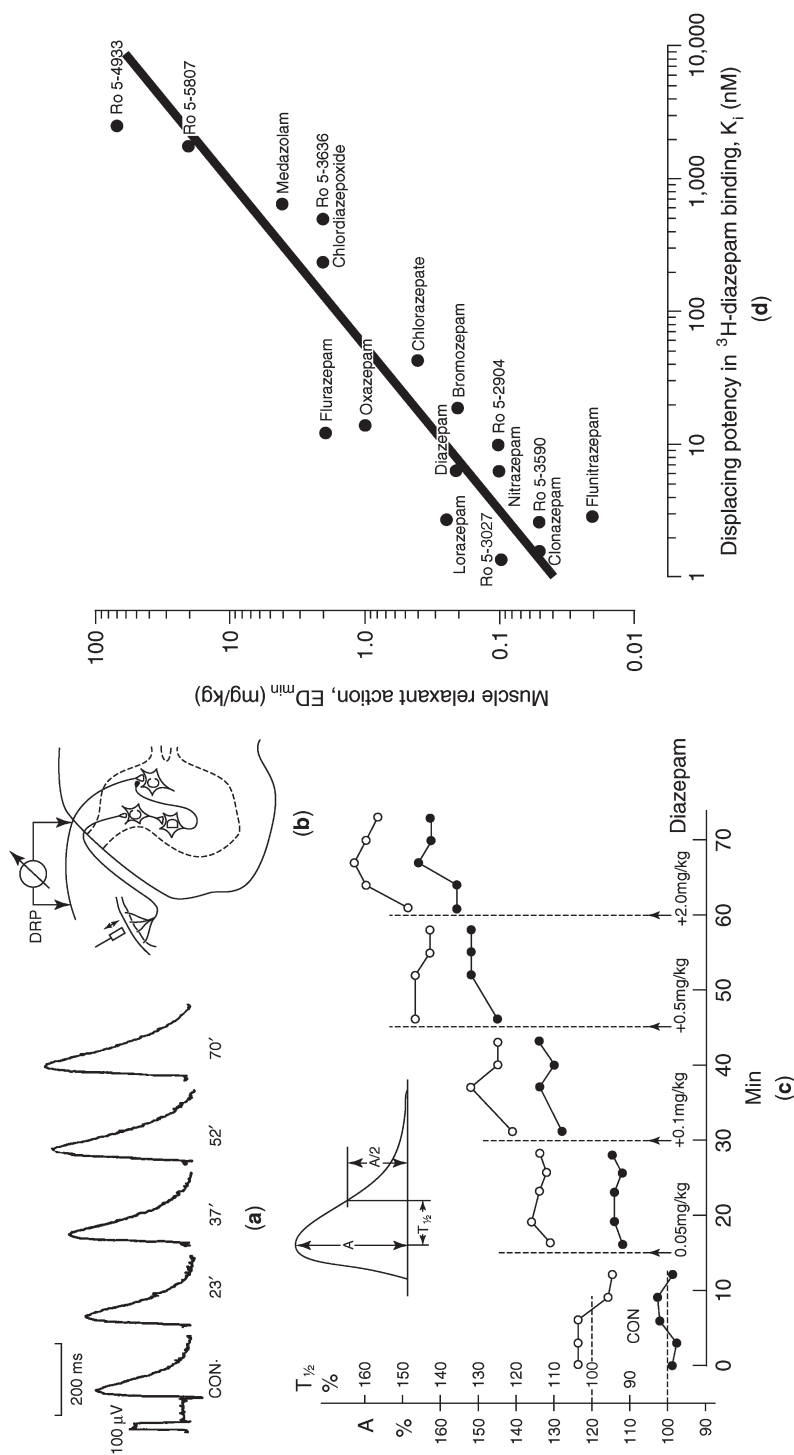

Figure 12.16 First demonstration of an enhancement of presynaptic inhibition in the vertebrate central system by a benzodiazepine. (a) The intensity of dorsal root potentials before (CON) and after four successive applications of diazepam following mechanical stimulation of the central foot pad. (b) Neuronal arrangement for stimulation of the foot pad and recording of the dorsal root potentials (DRPs). (c) The left-hand y axis shows the effect of successive applications of several concentrations of diazepam on the amplitude of the DRPs (A , filled circles). The right-hand y axis indicates the effect of diazepam on the time to half decay of the dorsal root potentials ($T_{1/2}$, open circles). after the use of short-acting drugs and development of tolerance and dependence also limit the current use of these drugs in the treatment of certain types of chronic anxiety disorders such as generalized anxiety disorder, epilepsy, and insomnia to the short-term medication [499, 510–512]. Anterograde amnesia, psychotic states, and alterations in sleep architecture have also been related to the use of some short-acting benzodiazepines. This has been the impetus for research into the development of effective anxiolytic compounds that do not have the side effects of the classical benzodiazepines [513, 514].

Development of such novel medicines devoid of side effects can be approached by creating compounds which display profound functional selectivity [594] or by targeting specific GABA_A receptor subtypes with subtype-selective drugs which will be expected to display fewer side effects, such as tolerance and dependence liability, because they will affect only a small population of GABA_A receptors [499–503]. In an attempt to create drugs with the desired therapeutic effects several compounds such as abecarnil [515–523], bretazenil [520, 524–530], divaplon [531–533], imidazenil [519, 534–538], zaleplon [539, 540], zolpidem [541, 542], and ocinaplon [385] have been synthesized.

Intrinsic activities of these compounds at different GABA_A receptor subtypes vary from partial to full positive allosteric modulators. For instance, abecarnil is a partial modulator at α_5 and a full positive modulator at α_1 - and α_3 -containing GABA_A receptors [600]. On the other hand, divaplon is a partial agonist at both α_5 - and α_3 -containing GABA_A receptors [520], and bretazenil and imidazenil both have low efficacy at a broad spectrum of GABA receptor subtypes [535]. These compounds exhibit fewer side effects associated with conventional anxiolytic benzodiazepines. A possible explanation for this diminished side-effect profile may be that the lower intrinsic efficacy of the GABA_A receptor partial agonists is probably sufficient to maintain low-efficacy responses such as anxiolytic and anticonvulsant actions but insufficient to induce sedation, myorelaxation, dependence, and ethanol potentiation, all of which may require high fractional receptor occupancy [543–546].

Accordingly, abecarnil is a potent anxiolytic and elicits little or weak effects in tests of motor incoordination and muscle relaxation and (in contrast to diazepam) exhibits a relatively weak ability to potentiate the effects of ethanol and barbiturates [516]. Interestingly, abecarnil was also found to be most effective with the fewest side effects at the lowest dosage studied in a double-blind, placebo-controlled clinical trial for treatment of generalized anxiety disorder [513]. The therapeutic safety, defined as the ratio between the anticonvulsant efficacy and the muscle relaxant action, is more favorable for abecarnil as compared to diazepam in rodents and baboon *Papio papio* [515]. Abecarnil also elicits potent anticonflict and taming effects with little sedative and ataxic effects in primates [521]. Chronic administration of abecarnil was found to elicit persistent anxiolytic and anticonvulsant effects without any amnesia in rats [522], and it did not induce tolerance or withdrawal syndromes in mice [518]. However, despite promising data obtained in animal models abecarnil failed to produce selective anxiolysis during clinical trials in humans [523].

The imidazobenzodiazepinone bretazenil (Ro 16-6028) acts as a partial allosteric modulator of benzodiazepine receptors producing only a 25% potentiation even at 100% receptor occupancy. These in vitro observations can be related to in vivo responses in animal models (mice) which indicate that bretazenil does not protect against seizures as well as the full allosteric positive modulator diazepam [495]. By

contrast, studies in humans and animals indicate that bretazenil elicits potent anticonflict and anticonvulsant activity and can provide these effects with a lower degree of sedation [524], dependence liability [527, 530], ethanol potentiation [535], motor impairments, and tolerance as compared to conventional benzodiazepines [544, 546–548]. Although bretazenil has lower abuse liability than diazepam, its development was apparently discontinued [529]. Likewise, divaplon elicits potent anticonflict activity and produces lower sedation [531] and tolerance [532, 533] as compared to diazepam.

Imidazenil is characterized as a partial allosteric modulator of GABA_A receptors. Behavioral experiments in the rat, using the Vogel conflict–punishment test, suggest that imidazenil is an anxiolytic. Imidazenil is devoid of sedation, ataxia, and ethanol potentiation and blocks the sedative and ataxic effects of diazepam in rats [534]. Furthermore, when administered with diazepam, imidazenil dose dependently blocks the side effects of sedation and ataxia typically associated with diazepam and thus, like flumazenil, appears to act as an antagonist on these unwanted responses [534]. It also completely attenuates the benzodiazepine-induced cognition deficit in monkeys [538]. Furthermore, it causes only low tolerance and dependence liabilities in rats [535]. Chronic treatment with a pharmacologically effective dose of imidazenil failed to induce tolerance to the effects of this drug on GABA_A receptor function in mouse brain [536].

Among the clinically used benzodiazepine site ligands only the hypnotics zaleplon and zolpidem have a pronounced preferential subtype selectivity [539–542] (Tables 12.1 and 12.2). Zaleplon was the first GABA_A receptor subtype preferring drug developed for the treatment of insomnia [539, 540]. Its binding affinity at α_1 - and α_3 -containing receptors is 8- to 20-fold higher than for receptors containing α_2 , α_4 , and α_5 subunits [549]. It has been suggested that such selectivity makes zaleplon a potent hypnotic with diminished rebound side effects.

Recent insights into the subtype specificity of benzodiazepine actions have provided guidelines for the development of subtype-selective benzodiazepine site ligands. Some of these novel developments are under experimental or clinical investigation [502, 550] and will be discussed below.

SL65.1498 (6-fluoro-9-methyl-2-phenyl-4-(pyrrolidin-1-ylcarbonyl)-2,9-dihydro-1*H*-pyrido[3,4-*b*]indol-1-one) is a pyridoindole that shows higher affinity for GABA_A receptors composed of α_1 , α_2 , and α_3 compared with α_5 . In addition, it is a full positive allosteric modulator at α_2 - and α_3 -containing receptors, whereas it acts as a partial positive modulator at α_1 - and α_5 -subunit-containing GABA_A receptors [551, 552]. Its selectivity for α_2 - and α_3 -containing GABA_A receptors may be responsible for the potent anxiolytic action in animal models (punished lever pressing, punished drinking, elevated plus maze, light/dark test) without impaired motor coordination (e.g., rotarod) or working memory (Morris water maze) [553].

Behavioral studies performed with α -subunit knockin mice suggest that ligands selective for GABA_A receptors containing α_2 subunits will be anxiolytic and will lack the sedative component [463]. However, ocinaplon, a pyrazolo[1,5-*a*]-pyrimidine, is an anxioreactive compound, which fails to show a selectivity for receptors composed of α_2 subunits. In fact, this compound, which has been shown to be an effective anxiolytic in preclinical and clinical tests, exhibits certain selectivity for α_1 -subunit-containing GABA_A receptors [385].

Discovery of subtype-specific positive or negative modulators of GABA_A receptors might be useful for the treatment of neuropsychiatric disorders extending

beyond the spectrum of pharmacological properties exhibited by classical benzodiazepines. In pursuit of a drug to enhance cognition, a series of novel ligands selective for the GABA_A receptors containing α_5 subunits have been developed. Some of these compounds have higher binding affinity for the GABA_A receptor containing the α_5 -subunit subtype compared to α_1 -, α_2 -, and α_3 -subunit-containing receptors (e.g., L-655,708) [554a]. Several compounds exhibit functional α_5 subunit selectivity as full/partial positive allosteric modulators [384], null modulators (antagonists) [554], or negative allosteric modulators [555, 556]. Such negative allosteric modulators of receptors containing α_5 subunits enhance cognitive performance in rats in the delayed matching-to-place Morris water maze test—a hippocampal-dependent memory task—without the convulsant or proconvulsant activity associated with nonselective GABA_A receptor inverse agonists [555, 556].

The novel benzodiazepine site ligand L-838,417 has comparable binding affinities toward GABA_A receptors containing α_1 , α_2 , and α_3 subunits but exhibits a threefold lower affinity toward receptors containing the α_5 subunit. L-838,417 is a null modulator at α_1 but acts as a full/partial modulator at α_2 -, α_3 -, and α_5 -containing receptors [384]. This compound has a high potency in anxiolytic (elevated plus maze and fear-potentiated startle) and anticonvulsant tests (pentylenetetrazole, audiogenic seizures) at doses that occupy less than 50% of benzodiazepine sites. Furthermore, at concentrations that occupy ~95% of benzodiazepine sites, L-838,417 failed to impair motor performance (rotarod test, chain-pulling test) [384].

Drug screening from traditional medicinal herbs has also attracted much attention in the hope of identifying novel therapeutics for the treatment of anxiety and related diseases [557]. The discovery of chrysin, one of the first flavonoids isolated from the plant *Passiflora coerulea* that interacts with the benzodiazepine binding site, marked the search for such natural anxiolytics [558–560]. A number of other naturally occurring flavonoids such as K36 [561], hispidulin [562], wogonin [563, 564], and related compounds [565–568] have been found to possess allosteric modulatory action at the GABA_A receptor complex.

K36 elicited significant behavioral responses in the elevated plus-maze test, increasing entries to the open arms (taken as an indicator of anxiolysis), with no change in locomotor activity. Moreover, in the hole-board, horizontal-wire, and rotarod tests K36 did not elicit significant sedation, myorelaxation, and motor incoordination at the anxiolytic dosages [561].

Hispidulin at concentrations of 50 nM and higher stimulated GABA-induced chloride currents acts as a positive allosteric modulator of the $\alpha_X\beta_2\gamma_{2S}$ ($X = 1, 2, 3, 5, 6$) GABA_A receptor subtypes. In contrast to diazepam, hispidulin modulated the $\alpha_6\beta_2\gamma_{2S}$ GABA_A receptor subtype. When fed to seizure-prone Mongolian gerbils (*Meriones unguiculatus*) in a model of epilepsy, hispidulin [10 mg/kg body weight (BW) per day] and diazepam (2 mg/kg BW per day) markedly reduced the number of animals suffering from seizures to 30 and 25% of animals in the respective treatment groups, versus 80% in the vehicle group after seven days of treatment [562]. Mice that received oral wogonin (7.5–30 mg/kg) exhibited a reduction in measures characteristic of anxiolytic action and similar to those elicited by diazepam in the elevated plus-maze test while showing no sign of sedation [564].

Naturally occurring flavonoids often bind to the benzodiazepine binding site with only moderate affinities. However, through synthesis of chemical libraries and molecular modeling of the flavonoid binding to the pharmacophore of the benzodia-

zepine binding site [569–572], several groups have been able to generate synthetic derivatives with higher affinities with allosteric properties varying from positive allosteric modulators to compounds devoid of intrinsic activity (antagonists) [573–576].

12.24 BENZODIAZEPINE BINDING SITE OF GABA_A RECEPTORS

Present evidence suggests that GABA_A receptors are the only effector sites of benzodiazepines in the CNS. An additional recognition site for benzodiazepine binding is located in peripheral tissue, but this is structurally and functionally unrelated to GABA_A receptors. The so-called peripheral benzodiazepine receptor is located on an 18-kDa protein in the inner mitochondrial membrane (for review see [577]). This review will focus on the recognition sites located in nervous tissue.

The nervous tissue-specific benzodiazepine (BZ) binding site has been shown to be located at the interface between the α and γ subunits, with residues from each subunit contributing to the binding site [294, 578–583] (Fig. 12.5). Photoaffinity labeling of the receptor by the benzodiazepines [³H]flunitrazepam and [³H]Ro15-4513 has been performed in order to identify residues that are part of the binding site [584–591]. The residues H101 (rat numbering) [588, 591–593] and P97 [591] have been shown to be the major sites of incorporation of [³H]flunitrazepam into the α_1 subunits. The amino acid(s) photolabeled by [³H]Ro15-4513 are contained within a subunit fragment extending from residue 104 to the C-terminus of the α_1 subunit [592], possibly within amino acids 247–289 spanning the end of TM1 to the beginning of TM3 [589]. The results from a recent study suggest that [³H]Ro15-4513 is photoincorporated into α_1 Y209 and in homologous positions in the α_2 and α_3 subunits [590].

Extensive mutagenesis experiments have also identified other α_1 residues implicated in benzodiazepine binding. The significance of α_1 H101 was initially demonstrated by substituting arginine, the native residue at the homologous position in α_4 and α_6 subunits [594, 595, 751, 752]. Substitution of histidine-101 by arginine resulted in a 500–800-fold decrease in the binding affinity of classical benzodiazepines [594, 595, 751, 752]. Experiments with receptor subunits in which residues suspected of facing the interior of the binding pocket were mutated to cysteine identified the position of classical BZ ligand (diazepam) binding relative to α_1 H101 by using BZ ligands carrying cysteine-reactive groups to link to mutated receptor subunits. The results point to interactions with the C-7 position of diazepam. Interestingly, at the functional level, the reacted receptor was irreversibly stabilized in an allosterically stimulated state [754].

The following residues in the α_1 subunit were shown to alter either benzodiazepine sensitivity in functional assays or benzodiazepine affinity in binding studies: Y159 [454], Y209 [291, 454], T162 [595], G200 [596–598], T206 [454], V211 [599], and I215 [600]. In the γ_2 subunit M57 [292] and Y59 [601] were found to be essential determinants for conferring high affinity for classical and atypical benzodiazepines. The γ_2 F77 residue is absolutely crucial for recognition of classical benzodiazepine ligands [290, 602, 603]. It should be noticed that this residue is homologous to F64 in the α_1 subunit, which has been previously shown to be a key determinant of the GABA binding site, suggesting conservative motifs between different ligand binding sites on the GABA_A receptor [290, 431, 448, 603] (Fig. 12.11). By analogy to the GABA binding pocket the residues A79 and T81 which are clustered on a β strand

around F77 are found to line up part of binding pocket [288, 601]. The residue γ_2 M130 is required for high-affinity binding of benzodiazepine binding site ligands [292, 602, 603]. Finally, a threonine residue at position 142 of the γ_2 subunit is implicated in the efficacy of benzodiazepine binding site ligands [604].

Residues identified in the BZ binding site can be divided into two groups: The first group affects only binding and the second both binding and allosteric modulation. Among those residues affecting allosteric modulation are α_1 H101, γ_2 77, and γ_2 T142. Receptors containing α subunits carrying point mutations in residues homologous to α_1 H101 exhibit lower affinity and altered efficacy for various BZ site ligands: changing partial allosteric modulators into full positive modulators (bretazenil) [752], null modulators into positive modulators (Ro15-1788) [751, 753], and partial negative modulators into positive modulators (Ro15-4513) [751, 752], thus demonstrating the importance of α_1 H101 to allosteric modulation.

In the γ_2 subunit, mutagenesis experiments have identified two amino acids, γ_2 F77 and γ_2 T142, that may play a role in the efficacy of BZ ligands. The γ_2 T142S mutation alters the efficacy of several BZ ligands; both the null modulator (Ro15-1788) and a partial negative modulator (Ro15-4513) were converted to partial positive modulators [604]. The γ_2 F77L [290, 757], γ_2 F77I [290], and γ_2 F77W [290], mutations enhanced diazepam positive allosteric modulation, even though the binding affinity of diazepam was reduced.

12.25 STRUCTURAL DETERMINANTS OF ALLOSTERIC MODULATION BY BENZODIAZEPINES

The binding of benzodiazepines changes the properties of the GABA_A receptor, but what is changed and how does the change occur? Historically, benzodiazepines were thought to act by binding to the benzodiazepine binding site and causing a change in receptor conformation via allosterism. In the case of positive allosteric modulators, the apparent affinity of the neurotransmitter recognition site for the agonist, GABA, increases, and negative allosteric modulators decrease receptor affinity for GABA [15, 294, 427]. Although this simple hypothesis has been in use since 1977, it was not until the late 1990s that data underlying both the molecular and mechanistic aspects of allosteric modulation started to emerge.

Allosteric modulation is a complex phenomenon, but as in the case of activation of ligand-gated ion channels by agonists, a multistep mechanism following binding of modulators is easily envisaged. The first step is chelation during which the ligand, upon binding, coordinates separate regions of the BZ binding site into a relatively rare conformation that causes the second step, the triggering of a conformational change in the whole receptor protein, that alter either one or both agonist binding site(s).

Rogers et al. [747] proposed an allosteric model in which diazepam increases the rate of entry into the singly bound closed state, although it was not known whether the increased rate occurs at one or both GABA recognition sites. In 1996, Lavoie and Twyman proposed an allosteric model in which diazepam accelerates the rate of GABA association at one of the sites, but the identity of each site was not specified [748]. Williams and Akabas [129], using molecular biology techniques combined with electrophysiology, subsequently determined that when certain amino acids in TM3

of the α subunit are mutated to cysteine a cysteine-reactive agent modifies two of these residues when the receptor is exposed to GABA and diazepam. The results suggest that diazepam binding changes α -subunit conformation such that only one mutated residue is accessible to modification, whereas when the GABA binds, the second or both residues are accessible.

Baur and Sigel [464] used receptors formed by concatenated subunits in which it is possible to destroy selectively one of the two agonist sites introducing point mutation. They found that both receptors with either site 1 or site 2 destroyed could be modulated by diazepam. This argues against the hypothesis that only one agonist site is altered by the binding the ligand to the benzodiazepine recognition site and suggests that modulation is not limited exclusively to one of the two agonist binding sites.

But what are the structural elements involved in transduction of allosteric modulation of GABA_A-R induced by classical BZs and how the mechanism of allosteric modulation is conceived given the fact that there are negative, null, and positive allosteric modulators? One study showed that α/γ chimeric receptors carrying a stretch of 167 aminoacids from N-terminal domain of the γ_{2S} subunit are able to bind BZ site ligands [749]. Although certain chimeric receptors exhibit wild-type binding properties and retain sensitivity to negative allosteric modulators, positive allosteric modulators display reduced efficacy in functional experiments. The stretch of amino acids from P161 to L187 on the α_6 subunit contains a region responsible for the functional positive allosteric action of Ro15-1788 on $\alpha_6\beta_2\gamma_2$ receptors [753]. However, the results of both studies agree that additional domains are important for conversion of binding into allosteric modulation.

Perhaps not too surprisingly, domains implicated in the transduction of agonist binding to channel gating in the α and β subunits are playing the very same role in transduction of allosteric modulation in the γ subunit. There is a body of evidence implying that the same parts of GABA_A receptors that are involved in the transduction of agonist binding to gating are also important for allosteric modulation—the TM1 and TM2 domains and the TM2–TM3 linker of the γ_{2S} subunit.

Studies using chimeric receptors and amino acid replacement at key residues in subunits demonstrate that the following two groups of residues were involved in transduction of conformational change induced by binding of BZ site ligands into modulation of receptor function: residues γ_2Y235 , γ_2F236 , γ_2T237 in TM1 [746]. In the TM2 segment, the part of the receptor forming the channel pore, residues γ_2S280 , γ_2T281 , and γ_2I282 were implicated in the disruption of allosteric modulation [746]. On the TM2–TM3 loop itself only one residue implicated in allosteric modulation by BZ ligands— γ_2S291 , has been so far identified [289].

Thus, allosteric coupling between the benzodiazepine and agonist recognition sites requires residues not only in the LBD [749] but also in the TM1 and TM2 domains [746] as well as the TM2–TM3 linker of the γ subunits [289, 463, 746]. When taken together the data suggest an alternative hypothesis for BZ modulation whereby binding of a benzodiazepine recognition site ligand results in a conformational change in the γ subunit that is transferred to the γ subunit TM2 domain via TM1 and the TM2–TM3 linker region. Destabilization of the γ_2 -subunit TM2 domain can in turn perturb the stability of TM2 in the α and β subunits that can lead to channel opening. This was observed by Downing et al. [758] in experiments with $\alpha_1L263S\beta_2\gamma_2$ receptors using diazepam and flurazepam; interestingly, openings gated by

flurazepam were inhibited by the BZ null modulator (antagonist) Ro15-1788. Thus, conformational instability induced in TM2 segments of other subunits can either shift the equilibrium toward the open state or be transferred back to the LBD through TM1, loops 2 and 7, and the TM2–TM3 linker, changing the conformation of the α/β -subunit interfaces that harbor agonist sites, subsequently affecting the kinetics of GABA binding to both agonist binding sites [289, 464]. The role that is played by residues located within the LBD in transduction of conformational changes remains to be determined. Additionally, the role, if any, of the low-affinity benzodiazepine site [750], which is also located in the TM region and involved in allosteric modulation of GABA_A receptors by ligands of the BZ site at high concentrations [750, 755, 756], remains to be established.

12.26 BENZODIAZEPINE BINDING SITES COMPOSED OF DIFFERENT α - AND γ -SUBUNIT ISOFORMS

Different α - and γ -subunit isoforms can assemble to form benzodiazepine recognition sites with different pharmacological properties. GABA receptors have been classified pharmacologically into diazepam-sensitive receptors that recognize classical, 5-phenyl-1,4-benzodiazepines (e.g., diazepam and flunitrazepam) and diazepam-insensitive receptors that do not recognize these ligands (Fig. 12.20) [605–607].

Diazepam-sensitive receptors can be further subdivided by their affinity to a triazolopyridazine, CL-218,872. The α_1 -containing receptors have a high affinity for CL-218,872 and are referred to as type I benzodiazepine receptors. Receptors composed of α_2 , α_3 , or α_5 subunits have a low affinity for CL-218,872 and are referred to as type II benzodiazepine receptors [608, 609]. Data showing the influence of the α -subunit isoform on the receptor pharmacology are summarized in Tables 12.1 and 12.2.

The term *benzodiazepine receptor* derives from the era in which ligand binding and electrophysiology were carried out on tissue preparations and neurons but it was not

Figure 12.20 Schematic view of N-terminal and TM domain of the γ subunit. Residues located in TM1, TM2, and TM2–TM3 linker that are implicated in the transduction of allosteric modulation induced by benzodiazepine site ligands are shown in the circles. The grey circle represents part of receptor discovered in studies of chimeric subunits by Boileau et al [749].

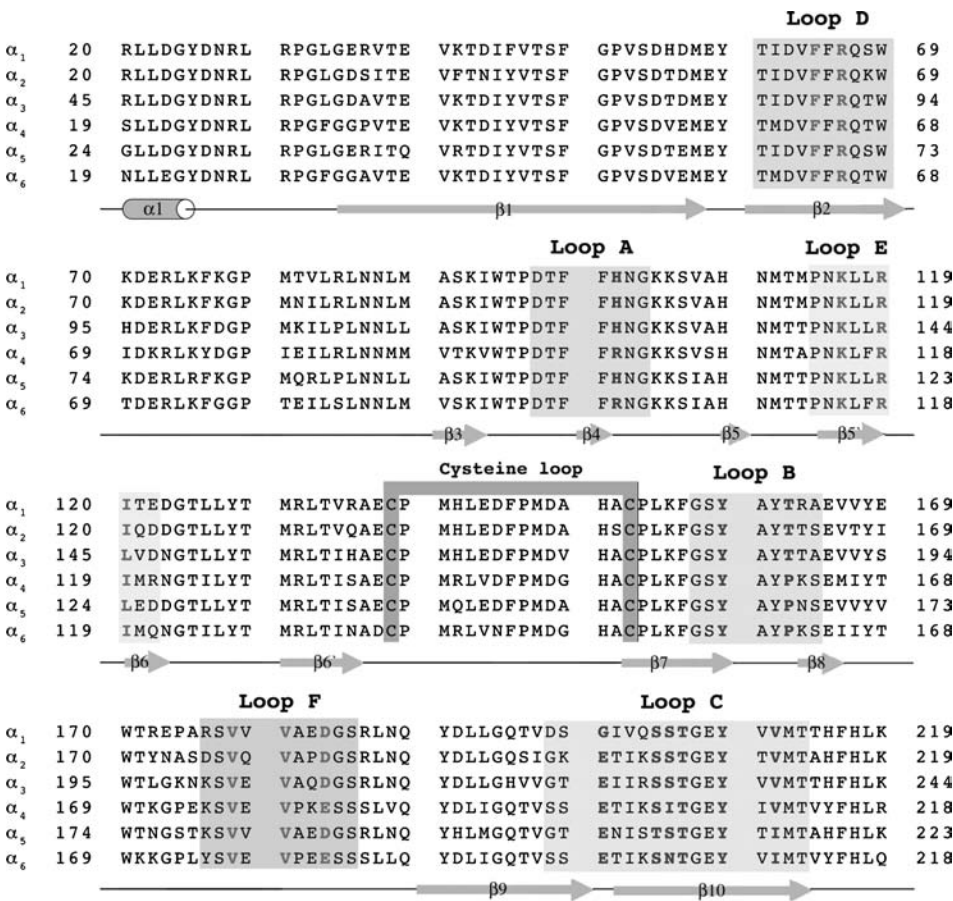

Figure 12.21 Alignment of the ligand binding domains of the GABA_A receptor α subunits. Residues forming the cysteine loop are highlighted in grey. The colored boxes are six regions, known in the six-loop agonist binding site model: loops A (green), B (pink), C (light brown), D (blue), E (cyan), F (dark green). Residues thought to form agonist binding site are in bold red, those implicated in the formation of the benzodiazepine binding site are in bold blue. Precursor peptide sequences of human subunits were obtained from NCBI (access codes: α_1 : P14867; α_2 : P47869; α_3 : P34903; α_4 : P48169; α_5 : P31644; α_6 : Q16445). Ligand binding domains were aligned to the mature peptide sequence of the α subunit using MaxHom [744] at Predict Protein (<http://www.predictprotein.org/>). (See color insert.)

known conclusively whether the functionally coupled benzodiazepine recognition site was on or associated with the type A GABA receptor. Evidence for a physical linkage between the two became possible once it was determined that multiple subtypes of the receptor existed and the subtypes were cloned. Mutagenesis experiments described in this review have demonstrated that both the GABA and benzodiazepine recognition sites are located on the GABA receptor. Whereas usage of the term benzodiazepine receptor is no longer justified, *benzodiazepine recognition site agonist*, *antagonist*, and *inverse agonist* persist as a shorthand notation when discussion focuses specifically on the benzodiazepine recognition site.

The relative preference of CL-218,872 and zolpidem toward α_1 -containing receptors (as compared with other α subunits) is conferred mainly by α_1 T161 [595, 623], α_1 G201 [596, 597], α_1 S205 [595, 623], and α_1 V211 [599]. It is noticeable that the subunits conferring the higher affinity to zolpidem have the smaller amino acid residues at both positions 201 and 211, suggesting a steric role for these residues in benzodiazepine selectivity. It was proposed that a similar mechanism also underlies more than 1000-fold decrease in affinity for diazepam, flunitrazepam, zolpidem, and CL-218,872 at α_6 -containing receptors compared to those having the α_1 subunit [598, 599, 606, 625]. α_6 N204 is another residue conferring insensitivity of α_6 -subunit-containing receptors to β -carboline, β -CCE. Introduction of a point mutation α_6 N204S or α_6 N204I found in the homologous position of α_1 or α_4 subunits restores affinity [625].

Many studies [586, 587, 616, 617, 626] indicate that the γ subunit also contributes significantly to the properties of the benzodiazepine recognition site (Fig. 12.21). GABA_A receptors containing γ_1 or γ_3 subunits have a lower affinity for most of the classical benzodiazepines compared to receptors composed of γ_2 subunits. In addition, γ_1 -containing receptors have a lower affinity for the antagonist Ro15-1788 than those receptors containing γ_2 or γ_3 subunits [150, 602, 615]. Data showing the influence of the γ -subunit isoform on GABA_A receptor pharmacology are summarized in Tables 12.3 and 12.4.

Two amino acid residues are determining the selectivity of zolpidem for γ_2 -subunit-containing receptors [290, 292, 602]. These are γ_2 F77 and γ_2 M130; the γ_1 subunit has an isoleucine (γ_1 I79) at a position homologous to γ_2 F77 and additionally γ_1 and γ_3 subunits contain a leucine at a position homologous to γ_2 M130 (γ_1 L132 and γ_3 L133). Introduction of the point mutations γ_1 I79F and γ_1 L132M in the γ_1 subunit and γ_3 L133M in γ_3 restores zolpidem affinity [292, 602]. Introduction of the point mutations γ_1 I79F, γ_1 L132M in γ_1 subunit and γ_3 L133M in γ_3 restores zolpidem affinity [292, 602]. A third region important for zolpidem affinity, was located recently downstream from these two residues in the Loop F of γ_2 subunit; residue γ_2 R194D was necessary for high affinity binding of the zolpidem, but not flunitrazepam [624].

12.27 MODULATION OF GABA_A RECEPTORS BY NEUROSTEROIDS, ANESTHETICS, ALCOHOLS, AND ANTICONVULSANTS

Neurosteroids [627–632], volatile [633], intravenous, and general anesthetics [634–641], alcohols [642–645], loreclezole, tracazolate, and related anticonvulsants [646–651] and allosteric antagonists can all modulate GABA_A receptor function [652–654] (see Fig. 12.22). Selye et al. [655] were the first to demonstrate that neuroactive steroids, their naturally occurring metabolites, and synthetic steroid derivatives can produce a rapid depression of CNS activity by nongenomic mechanisms [656, 657]. Neurosteroids are synthesized from cholesterol locally in brain cells, independent from their peripheral concentrations [632, 656, 658, 659]. 5α -Reductase transforms progesterone to 5α -dihydroprogesterone (5α -DPH), which can act on gene transcription via progesterone receptors of brain cells. 5α -DPH is reduced by 3α -hydroxysteroid oxidoreductase to allopregnanolone.

Neurosteroids acting at GABA_A receptors can be divided into two functional groups: uncharged, which act as positive allosteric modulators [199, 273, 660], and

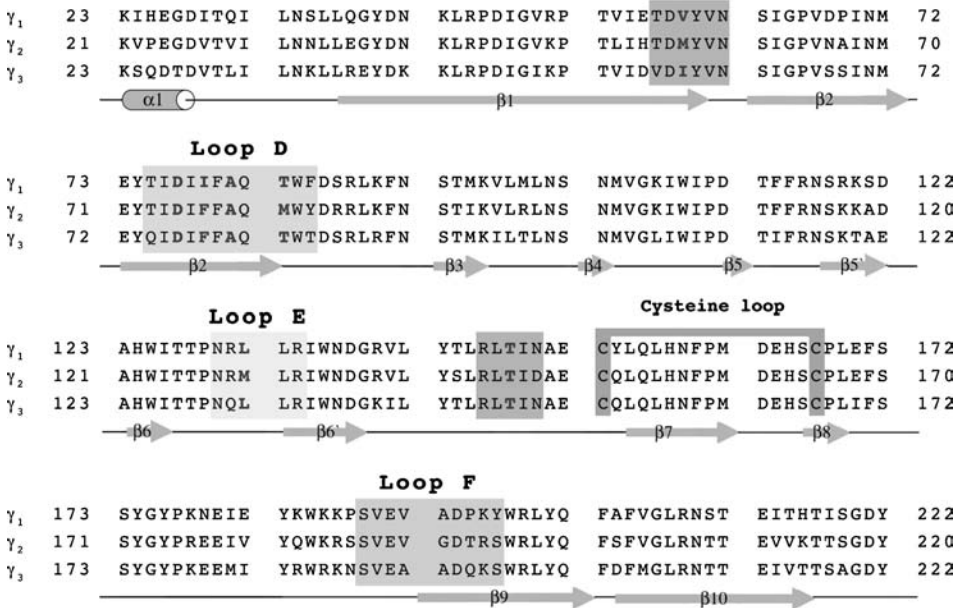

Figure 12.22 Alignments of the ligand binding domains of the GABA_A receptor γ subunits. Residues forming the cysteine loop are highlighted in grey. The colored boxes are regions known in the six-loop agonist binding site model: loops D (blue), E (cyan), F (dark green). Pink boxes contain residues that are not assigned to any “loops” but are important for benzodiazepine binding or allosteric modulation. Residues thought to be implicated in the formation of the benzodiazepine binding site are in bold blue. Precursor peptide sequences of human subunits were obtained from NCBI (access codes: γ_1 : NP_775807.2; γ_2 : P18507; γ_3 : Q99928). Ligand binding domains were aligned to the mature peptide sequence of the γ_1 subunit using MaxHom [744] at Predict Protein (<http://www.predictprotein.org/>). (See color insert.)

charged, negative allosteric modulators of receptor function [629–631, 661]. Enhancement of submaximal GABA_A receptor currents occurs through an increase in both channel open frequency and open duration [271, 273, 274, 628]. Charged neurosteroids inhibit GABA-gated channel openings by enhancing receptor desensitization and stabilizing desensitized states [662, 663].

Pregnanolone and allopregnanolone have been associated with anxiolytic effects in mice on the elevated plus-maze test [664–666]. Synthetic analogs of neuroactive steroids have been investigated for potential use as anxiolytics, anesthetics, and anticonvulsants [545, 657, 667, 668].

Ganaxolone (3-hydroxy-3-methyl-5-pregnan-20-one) is an orally active synthetic analog of allopregnanolone and a positive allosteric modulator of GABA_A receptor [545, 667, 669]. Ganaxolone is a more effective blocker of the anxiogenic effects induced by pentylenetetrazol in mice than diazepam [670]. Wieland et al. [671] have reported that 3 β -substituted analogs of the endogenous neuroactive steroid 3 α -hydroxy-5 α -pregnan-20-one (e.g., 3 β -ethenyl-3 α -hydroxy-5 α -pregnan-20-one, or Co 3-0593) exhibit anticonvulsant activity against pentylenetetrazol-induced seizures in mice and rats (median effective dose ED₅₀ values of 5.6 and 11.5 mg/kg i.p.,

respectively). In addition, Co 3-0593 produces anxiolytic effects in the Geller–Seifter test, comparable to benzodiazepines. Furthermore, the anxiolytic activity of Co 3-0593 remains even after chronic administration, suggesting an absence of tolerance. This compound does not affect the acquisition of a learned response at both anticonvulsant and anxiolytic doses. However, at higher doses it induces rotarod performance deficits that are further enhanced by ethanol [671]. These findings suggest that synthetic neurosteroids that can easily cross the blood–brain barrier may represent a novel class of potentially useful therapeutic agents [666, 672, 673].

GABA_A receptors are particularly sensitive to many anesthetic agents, and there is a strong correlation between the concentrations of these compounds that affect receptor function and their anesthetic potencies [674–676]. A wide range of compounds modulate GABA_A receptors, including volatile anesthetics such as isoflurane [677–680], halothane [674], and enflurane [676, 681], as well as nonvolatile agents such as pentobarbital, etomidate, etifoxine, and propofol [679, 680, 682, 683]. These compounds can, at high concentrations, directly gate the ion channel of the GABA_A receptor in the absence of GABA [631, 684–686]. At low concentrations they modulate GABA-induced openings [636], and, depending on the type of compound, this potentiation of GABA-gated currents appears to alter receptor activation/deactivation and/or desensitization [274, 687–689].

Small alcohols such as ethanol and trichloroethanol might bind to a domain on or associated with GABA_A receptors and produce anxiolytic and hypnotic effects [690]. Ethanol appears to interact more readily at physiologically relevant concentrations with receptors containing a δ subunit [690]. Interestingly, the hypnotic effects and potencies of the *n*-alcohols increase with carbon chain length. Thus, *n*-hexanol and *n*-octanol produce greater effects at lower concentrations than does ethanol [691].

Behavioral studies have shown that loreclezole, tracazolate, etazolate, and etifoxine, compounds structurally unrelated to benzodiazepines and neurosteroids, possess anxiolytic and anticonvulsant activities [646–651, 692–694]. Compared with the standard benzodiazepine chlordiazepoxide, these compounds are 2–20 times less potent as anxiolytics but, surprisingly, display a much larger window of separation between the anxiolytic effect and potential side effects (sedation, motor incoordination, and its interaction with ethanol and pentobarbital) in mammals [650, 693]. Binding and electrophysiological experiments have demonstrated that these compounds bind to GABA_A receptors via an allosteric site that differs from the benzodiazepine and neurosteroid modulatory sites [250, 694–697].

12.28 ALLOSTERIC SITES WITHIN TRANSMEMBRANE DOMAIN OF RECEPTOR SUBUNITS

A large body of evidence has been collected suggesting that neurosteroids, anesthetics, barbiturates, alcohols, and a number of other drugs share overlapping structural determinants for their actions on the GABA_A receptor [701].

A set of residues located in the TM 1–4 of GABA_A receptor α and β subunits confers potency to various clinically used compounds (Figs. 12.23 and 12.24). Residues implicated in the formation of these binding sites are located within homologous domains of α and β subunits. It is worth noting that the same

Figure 12.23 Compounds acting via binding sites located within transmembrane domains of GABA_A receptor subunits. Volatile anesthetics (halothane and isoflurane), general anesthetics (propofol, pentobarbital, and etomidate), anticonvulsants with anxiolytic properties (lorelezole, mefenamic acid, etifoxine), allosteric antagonists (furosemide and amiloride), and neurosteroids [pregnanolone, allopregnanolone, pregnenolone sulfate (PS) and 5 α -THDOC].

Figure 12.24 Schematic view of the membrane part of GABA_A receptor α subunit with residues implicated in formation of different allosteric binding sites.

transmembrane regions have been described as integral parts of the channel gating domain of the GABA_A receptor [128, 434] and other ligand-gated ion channels [223, 224, 277, 442].

Mutation of residue α_1 G223F located on the TM1 segment of α subunits reduces gating induced by pentobarbital and propofol [745]. Mutation of another residue, α_2 L232F, which is also located on TM1 reduces potentiation by halothane [698]. It was also found that a single amino acid in the α_6 -subunit TM1 segment, α_6 I230, confers sensitivity to furosemide inhibition [653, 699].

In the TM2 and TM3 segments α_1 S270 and α_1 A291 residues are part of the binding site for ethanol [643, 645, 700], halothane, isoflurane, and propofol [702–707] (Fig. 12.23). Mutation of these residues greatly reduces potentiation of GABA-gated currents by these compounds. Interestingly, the α_1 -subunit TM4 segment harbors an additional set of complementing residues of this allosteric site. Introduction of a tryptophan mutation in residues α_1 Y411, α_1 T414, and α_1 Y415 reduces the ability of isoflurane, halothane, and chloroform to potentiate GABA-gated currents [705].

Residues β_2 G219F, β_2 N265, and β_2 M286 located on TM domains 1–4, which are homologous to α_1 G232, α_1 S270, and α_1 A291, confer sensitivity to inhaled, general anesthetics and anticonvulsants [637, 638, 640, 641, 647, 651, 653, 700, 708–710] (Fig. 12.24).

Mice with β_2 N265S knockin mutation lack the sedative effects produced by etomidate [369] whereas the β_3 N265S mutation renders mice insensitive to the anesthetic effects of propofol and etomidate, with a small reduction in potency of volatile anesthetics [370].

Selectivity of loreclezole for β_2/β_3 - over β_1 -subunit-containing receptors is determined by the TM3 residue β_2 N289/ β_3 N290. Mutating a single serine to asparagine in the β_1 subunit (β_1 S289N) is sufficient to confer loreclezole sensitivity to β_1 -containing receptors [711].

Residues conferring sensitivity to GABA_A receptors for Zn^{2+} were identified in the TM2 domain. Mutations of residues β_2 H267 and β_2 G270 located close to the entrance of the channel pore reduce zinc inhibition about 650-fold [712–714].

Recent findings suggest that the action of some neurosteroids on GABA_A receptor is mediated through sites formed by the TM part of receptor subunits. Thus, it was discovered that modulation of ρ -containing receptors by allotetrahydrodeoxycorticosterone (5 α -THDOC), 5 β -pregnane-3 α -ol-20-one (pregnanolone), and 5 β -dihydroprogesterone (5 β -DHP) is dependent on residue ρ_1 I307, which is homologous to β_2 N265/ α_1 S270 [715]. Experiments using α_1/ρ_1 chimeric receptors indicate that there is a region from TM4 to the C-terminus of the GABA_A receptor α_1 subunit that is critical for the effects of neurosteroids [716].

12.29 CHANNEL BLOCKERS AND THEIR BINDING SITE

Channel blockers antagonize GABA-elicited currents in a noncompetitive fashion [717–721] and act as convulsants in vivo (Fig. 12.25). Picrotoxinin, U-93631, TBPS, and some insecticides are thought to bind at a single binding site located within the channel pore [468, 469, 722–724].

The binding site of channel blockers is formed by residues located on TM2 segments of both α and β subunits (Fig. 12.26). Residues conferring sensitivity to picrotoxinin and TBPS are α_1 V257 and α_1 T261 [722, 723] and β_2 A252 and β_2 L253 (Fig. 12.27) [468, 469]. The β_2 T246 located on the linker between TM1 and TM2 segments affects the potency of the convulsant compound pentylenetetrazole [724].

Figure 12.26 Chemical structure of some channel blocker of GABA_A receptors.

Figure 12.27 Schematic view of the membrane domains 2 and 3 of α and β subunits of the GABA_A receptor with residues forming binding site for the channel blockers.

12.30 MODULATION OF GABA_A RECEPTORS VIA UNIDENTIFIED ALLOSTERIC SITES

The structural determinants of the recognition sites for a number of compounds that allosterically modulate or act through GABA_A receptors directly have not been identified thus far.

The γ -butyrolactones are a class of compounds that interact with the GABA_A receptor at a site different from those of benzodiazepines or barbiturates [725, 726]. Competition binding experiments using [³⁵S]TBPS as a radioligand suggest that γ -butyrolactones bind at the picrotoxinin site [727–729]. However, the potentiation of GABA responses by these compounds is retained at receptors containing a mutation that disrupts the picrotoxinin recognition site [730–732].

A number of fatty and unsaturated acids modulate GABA_A receptor function. Arachidonic, eicosatetraenoic, and oleic acids inhibit currents elicited by GABA and muscimol in brain preparations and recombinant GABA_A receptors in a dose-dependent manner [733–735]. Thyroid hormones such as L-triiodothyronine (T₃) and L-thyroxine are also reported to interact with GABA_A receptors [736], and it has been suggested that the α_1 subunit imparts T₃ sensitivity [736]. The antihelminthic compound avermectin [737, 738], the anxiolytic anticonvulsant compounds chlormethiazole and trichloroethanol [739–741], polyamines such as spermine and spermidine [742], and antidepressants such as amoxapine and mianserin [743] have been reported to interact with GABA_A receptors, but the exact site of action of these drugs and their subunit requirements are not known.

13.1 INTRODUCTION

γ -Aminobutyric acid (GABA) is the major inhibitory neurotransmitter in the central nervous system (CNS) and as such plays a key role in modulating neuronal activity. GABA mediates its action via distinct receptor systems, the ionotropic GABA_A and metabotropic GABA_B receptors. Unlike GABA_A receptors that form ion channels, GABA_B receptors address second-messenger systems through the binding and activation of guanine-nucleotide binding proteins (G proteins). Hence, the effects of activating GABA_B receptors are slower and longer lasting than those of activating GABA_A receptors. GABA_B receptors were first demonstrated on presynaptic terminals where they inhibit neurotransmitter and neuropeptide release by suppressing a Ca^{2+} conductance or by exerting a direct effect on the release machinery. Subsequent studies also showed the presence of GABA_B receptors at postsynaptic sites where they inhibit neuronal excitability by increasing a K^{+} conductance. Therefore, GABA_B receptors can have either excitatory or inhibitory effects on the overall excitability in a neuronal network, depending on their cellular/subcellular localization and the temporal/spatial pattern of activation relative to other synaptic inputs.

Given this multitude of GABA_B functions it is not surprising that dysfunction of GABA_B-mediated synaptic transmission in the CNS is believed to underlie various nervous system disorders. For example, GABA_B receptors were linked to epilepsy, anxiety, sleep disorders, depression, addiction, and pain. GABA_B research, because of its medical relevance, has always attracted a great deal of attention in academia and industry. The prototypic GABA_B receptor agonist baclofen (β -chlorophenyl-GABA, Lioresal) was introduced to the market in 1972 and is still used to treat spasticity and skeletal muscle rigidity in patients with spinal cord injury, multiple sclerosis, amyotrophic lateral sclerosis, and cerebral palsy. In addition, the partial GABA_B agonist γ -hydroxybutyrate (GHB) (Xyrem) has recently been approved in different countries for such varied uses as general anaesthesia, the treatment of alcohol withdrawal and addiction, and, most recently, cataplexy associated with narcolepsy. Baclofen and other GABA_B agonists showed promising therapeutic effects in a whole range of other indications, but their side effects, including sedation, tolerance, and muscle relaxation, prevented further development. Many researchers in the field assumed that a dissociation of the therapeutic effects from the side effects would be achievable with more selective GABA_B drugs. This assumption was based on a large body of literature suggesting the existence of pharmacologically distinct GABA_B receptor subtypes in the brain. However, molecular cloning efforts resulted

in the identification of only three abundant GABA_B receptor complementary deoxyribonucleic acids (cDNAs), derived from two genes, *GABA_{B1}* and *GABA_{B2}*. Molecular heterogeneity in the GABA_B system is provided by the GABA_{B1} isoforms GABA_{B1a} and GABA_{B1b} that are generated from the same gene by alternative promoter usage. GABA_{B1a} and GABA_{B1b} differ in their extracellular domain and each assembles with the GABA_{B2} subunit to form pharmacologically similar heterodimeric GABA_{B(1a,2)} and GABA_{B(1b,2)} receptors. Much is now known about the roles of the individual subunits in the activation, assembly, and signaling of the heterodimer, which will be discussed in detail below. The existence of only two abundant molecular subtypes of GABA_B receptors was a surprise to many in the field who expected a variety of pharmacologically distinct GABA_B receptors, as predicted from the work on native receptors. Efforts therefore turned toward identifying GABA_B receptor-associated proteins, receptor modifications, and endogenous factors that possibly were responsible for generating pharmacological differences. We provide an overview on the current knowledge on protein interactions with GABA_B receptors. With the puzzling lack of pharmacologically distinct receptor subtypes, it became important to understand to which known GABA_B functions the cloned subunits contribute in vivo. To this end a number of laboratories disabled GABA_B genes in mice by gene targeting. Analysis of mice deficient for *GABA_{B1}* or *GABA_{B2}* confirmed that both GABA_B subunits are critical for the classical GABA_B responses in vivo. However, it also revealed that functional GABA_B receptors could exist in neurons that naturally lack GABA_{B2} subunits, which may add to the molecular and functional diversity of GABA_B receptors. A long-standing question in the field concerns the relationship between GABA_B receptors and the receptors for GHB, a metabolite of GABA and emerging drug of abuse. It is a matter of much debate whether specific GHB receptors exist and whether they are related to GABA_B receptors. This question was addressed using molecular tools and GABA_B knockout mice. Furthermore, we review recent studies that tried to establish a link between polymorphisms in GABA_B genes and congenital human diseases. Taking recent developments in the field into account, we also touch on the most promising indications for GABA_B drugs. Last but not least, the cloned receptors were used to establish high-throughput compound screens based on functional assays, which yielded the first allosteric compounds acting at GABA_B receptors. The features of these compounds will be discussed.

13.2 RECEPTOR STRUCTURE

13.2.1 Expression Cloning of GABA_B Receptors

It took close to 20 years after their discovery by Bowery and colleagues [1, 2] until GABA_B receptors were cloned. As with many neurotransmitter receptors, biochemical isolation was hindered by the lack of ligands that bind the receptor under solubilizing conditions and cell lines that express significant amount of receptor protein. Ultimately expression cloning using a high-affinity GABA_B radioligand resulted in the identification of two closely related cDNAs [3]. The two cDNAs derive from a single gene by alternative promoter usage and encode proteins of 960 and

844 amino acids, designated GABA_{B1a} and GABA_{B1b}. Recombinantly expressed GABA_{B1a} and GABA_{B1b} proteins have molecular masses of 130 kDa and 100 kDa, respectively, which are similar to the ones reported for native receptors. Sequence comparison revealed that GABA_B receptors belong to the family 3 (also named family C) of G-protein-coupled receptors (GPCRs), which also includes the metabotropic glutamate receptors (mGluRs), Ca²⁺-sensing receptors (CaS), vomeronasal receptors, taste receptors, and a number of orphan GPCRs.

While GABA_{B1} subunits showed many of the expected features of native GABA_B receptors in terms of structure and distribution, they surprisingly did not efficiently couple to their effector systems [4]. Moss and colleagues were the first to show that GABA_{B1} proteins are not transported to the cell surface but remain associated with the endoplasmic reticulum (ER) when expressed in heterologous cells [5]. This was taken to explain the 100- to 150-fold lower affinity for agonists that is observed with recombinant GABA_{B1} subunits when compared to native GABA_B receptors [3]. Presumably the failure to traffic to the cell surface prevents the interaction of GABA_{B1} subunits with G proteins in the plasma membrane, which is necessary to stabilize the high-affinity conformation of the binding site [6]. Ultimately, the identification of a second GABA_B subunit termed GABA_{B2} provided the necessary explanation [7–12]. In heterologous cells GABA_{B2} must be coexpressed with GABA_{B1a} or GABA_{B1b} to form a fully functional receptor. The GABA_{B2} subunit not only serves to escort GABA_{B1} to the cell surface but also appears to be the receptor component that mainly links to the G protein. This finding represented the first compelling evidence for heterodimerization among GPCRs. Until then it was thought that functional GPCRs mainly exist in the plasma membrane as monomers or homodimers. Recombinant heteromeric GABA_{B(1,2)} receptors couple to all prominent effector systems of native GABA_B receptors, that is, adenylate cyclase, Kir3-type K⁺ channels, and P/Q and N-type Ca²⁺ channels [13–15]. Moreover, when the GABA_{B2} subunit is coexpressed with GABA_{B1}, agonist potency more closely approximates that of native receptors. A 10-fold lower affinity compared to brain receptors is still observed for recombinant GABA_{B(1,2)} receptors, which may be explained by limiting amounts of the G protein in the heterologous cells [8].

13.2.2 Molecular Subtypes

When it became apparent that probably all GABA_B receptors in the vertebrate brain are the sole products of the *GABA_{B1}* and *GABA_{B2}* genes, much attention focused on subunit isoforms generated by alternative splicing. Many in the field wondered whether such isoforms encoded pharmacological differences and accounted for the heterogeneity observed with native GABA_B receptors. Rapidly numerous GABA_B splice variants were identified (recently reviewed in [16]). A close inspection of the gene structures indicates that not all proposed splice variants are real and that some do not occur across different species. While in most laboratories mixing and matching of splice variants did not produce GABA_B receptors with distinct functional and pharmacological properties, others reported differences that are, however, highly controversial. GABA_B isoforms may afford the means for a differential subcellular compartmentalization and/or coupling to distinct intracellular signaling pathways. To some extent a coupling to different effector systems could

mimic differential agonist pharmacology and explain some of the differences that were observed with native GABA_B receptors.

The most abundant GABA_B receptor isoforms are GABA_{B1a} and GABA_{B1b}, which exhibit dissimilarity in the extracellular domain (ECD) [3]. The GABA_{B1a} and GABA_{B1b} isoforms are the only variants that are highly conserved among different species. The first 147 amino acids of the mature GABA_{B1a} isoform are replaced in GABA_{B1b} with a sequence of 18 amino acids. Contrary to the general assumption, GABA_{B1a} and GABA_{B1b} are not generated by N-terminal alternative splicing. The distinct ECD in GABA_{B1b} results from the presence of an alternative transcription initiation site within the GABA_{B1a} intron upstream of exon 6, thereby extending exon 6 at its 5' end (Fig. 13.1) [17, 18]. Presumably, GABA_{B1a} and GABA_{B1b} use different promoters, with the GABA_{B1b} promoter being buried within GABA_{B1a} intron sequences (Fig. 13.2). Indeed, it was recently shown that multiple DNA regulatory elements, identified in the 5'-flanking regions, selectively regulate expression of GABA_{B1a} and GABA_{B1b} transcripts [19]. Alternative N-termini are rather exceptional for GPCRs and are not observed in any of the closely related family 3 GPCRs. Structurally, GABA_{B1a} differs from GABA_{B1b} by a pair of extracellular "sushi repeats," a common protein interaction module originally identified in proteins of the complement system. Sushi repeats, or SCRs (short consensus repeats) as they are also referred to, have yet to exhibit a function in the context of the GABA_B receptor. It is tempting to speculate that GABA_{B1a} is compartmentalized to specific subcellular regions by means of interaction of its sushi repeats with proteins in the neuron itself, in the extracellular matrix, or on the surface of neighboring cells. It was proposed that the GABA_{B1a} sushi repeats interact with the extracellular matrix protein fibulin; however, a physiological relevance for this interaction has yet to be demonstrated [20]. A recent report showing that the ECD 1 of a type B1 GPCR folds into a sushi repeat suggests that these protein-protein interaction modules are more common among GPCRs than previously thought [21].

Numerous studies indicate that GABA_{B1a} and GABA_{B1b} show differences in their spatial and temporal expression patterns [3, 8, 13, 22–29]. A pre- versus postsynaptic localization was suggested for both isoforms but due to the lack of selective pharmacological tools was never directly demonstrated [13, 23, 28]. A striking example of a differential expression of GABA_{B1a} and GABA_{B1b} is found in the cerebellum (Fig. 13.1) [13, 24]. GABA_{B1a} transcripts are mostly confined to the granule cell layer that comprises the cell bodies of the parallel fibers, which are excitatory to the Purkinje cell dendrites in the molecular layer. By comparison GABA_{B1b} transcripts are mostly expressed in Purkinje cells, the dendrites of which possess GABA_B receptors that are postsynaptic to GABAergic Basket and Stellate cells or glutamatergic parallel fibers. In dorsal root ganglia the density of GABA_{B1a} transcripts is high as opposed to GABA_{B1b} transcripts [28]. GABA_{B1b} protein is generally expressed at higher levels in the adult brain when compared to fetal brain, whereas the opposite is seen during development (Fig. 13.1) [18, 22, 25, 30]. These spatial and temporal differences in the expression of the GABA_{B1a} and GABA_{B1b} subunits highlight the separate transcriptional regulation and suggest distinct functional roles. A number of laboratories compared the pharmacological properties of GABA_{B1a} and GABA_{B1b} without detecting significant differences [8, 22, 31, 32]. However, there are isolated reports that claim that GABA_{B1a} and GABA_{B1b} can be separated by pharmacological or functional means [33–35]. Especially, the proposal

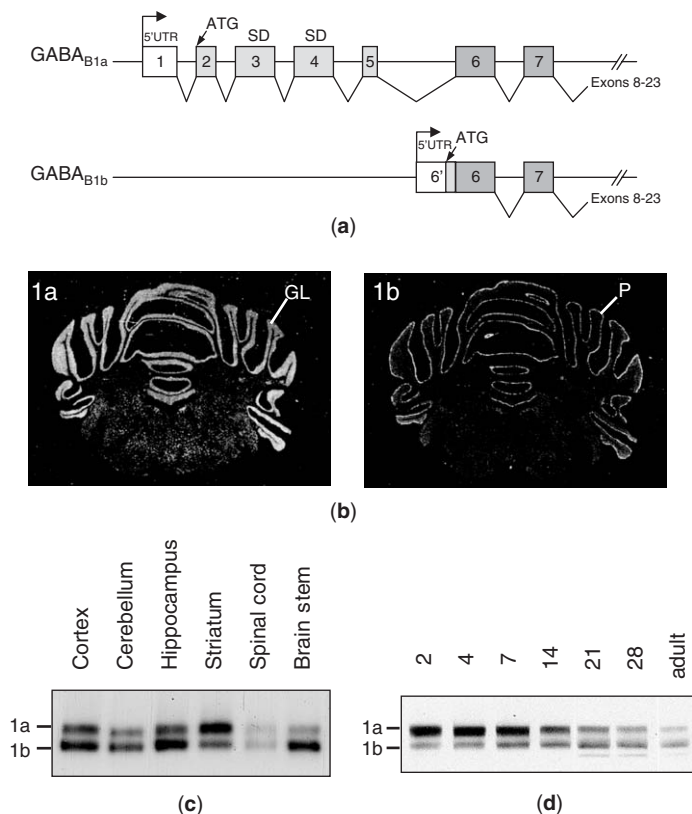

Figure 13.1 Differential expression of GABA_{B1a} and GABA_{B1b} transcripts. (a) Differential promoter usage results in generation of GABA_{B1a} and GABA_{B1b} transcripts. The GABA_{B1b} isoform uses an alternative transcription initiation site within the GABA_{B1a} intron upstream of exon 6. Thus the first 147 amino acids of the mature GABA_{B1a} isoform are replaced in GABA_{B1b} with a sequence of 18 amino acids. The amino terminal extracellular domains of GABA_{B1a} and GABA_{B1b} primarily differ by the presence of a pair of sushi domains (SDs) encoded by GABA_{B1a} exons 3 and 4. Exons are indicated as boxes (not drawn to scale). The transcription start sites (arrows) and translation initiation codons (ATG) are labeled. (b) Spatial distribution of GABA_{B1} transcripts in the cerebellum using isoform-specific riboprobes. GABA_{B1a} transcripts are predominantly observed in the granule cell (GL) layer, whereas GABA_{B1b} mRNA is present in the Purkinje cells (P). (c) Photoaffinity crosslinking of GABA_B receptor proteins. GABA_{B1a} and GABA_{B1b} are differentially expressed throughout the CNS. (d) Developmental expression of GABA_B receptors. GABA_{B1b} protein is generally expressed at higher levels in the adult brain compared with fetal brain, whereas GABA_{B1a} protein is more abundant during development. Numbers refer to postnatal days. (See color insert.)

that the anticonvulsant gabapentin is an agonist at GABA_{B(1a,2)}, but not at GABA_{B(1b,2)}, attracted a great deal of attention [33, 34, 36]. Not only was gabapentin suggested to be subunit specific, but it was also shown to selectively activate postsynaptic GABA_B receptors. This remains highly controversial, as a number of other laboratories were unable to reproduce these findings using similar and additional experimental approaches [37–39]. In these latter studies, no clear effect

of gabapentin on GABA_B receptors was seen in recombinant systems, in brain slice preparations or in vivo, even when using high concentrations of the drug.

Besides GABA_{B1a} and GABA_{B1b}, the existence of several additional GABA_{B1} isoforms was reported. However, genomic analysis only confirmed splice junctions consistent with the formation of GABA_{B1c} and GABA_{B1e} by exon skipping from a parent GABA_{B1a} transcript [18]. Whereas skipping of exon 4 in GABA_{B1c} would result in a protein lacking the second extracellular sushi domain, skipping of exon 11 in GABA_{B1e} would produce a truncated secreted GABA_{B1a} fragment through the introduction of a frame-shift stop codon in the ECD. The existence of protein expressed in vivo has not yet been demonstrated for any of these additional GABA_{B1} splice variants. With regard to GABA_{B2}, the available data strongly support that only the initially described transcript is expressed in vivo. Hence, it is now generally accepted that the molecular distinction in the GABA_B system is predominantly based on the subunit isoforms GABA_{B1a} and GABA_{B1b}, which each assemble with the GABA_{B2} subunit to form heterodimeric GABA_{B(1a,2)} and GABA_{B(1b,2)} receptors.

13.2.3 Surface Trafficking and Heteromerization

As the function of GABA_B receptors critically depends on heterodimerization, a quality control mechanism has evolved that prevents trafficking of unassembled GABA_{B1} subunits to the cell surface. It is now well established that this involves an ER retention/retrieval signal, the four amino acids RSRR, within the cytoplasmic tail of GABA_{B1} [5, 40, 41]. ER retention/retrieval signals of this type were also observed in a number of other multisubunit proteins, for example, the K_{ATP} channels [42] and *N*-methyl-D-aspartate (NMDA) receptors [43], where they control stoichiometry and surface expression of the channel complex. Similarly, it is thought that association of GABA_{B1} with GABA_{B2} masks its ER retention/retrieval signal, allowing for the functional heterodimer to exit the ER. However, the exact mechanism for ER anchoring and release is still unclear (see below). Within the RSRR motif of GABA_{B1} the serine residue and the third arginine are not absolutely critical for function, as they can be substituted by other amino acids [5, 40, 41]. It was proposed that the functionality of the RSRR motif of GABA_{B1} depends on surrounding sequences [44]. In particular, amino acid residues that are part of the coiled-coil domain and neighbor the RSRR motif N terminally were shown to be important for recognition of the RSRR motif. From these experiments it was concluded that the minimal ER retention sequence in GABA_{B1} is comprised of the amino acids QLQXRQQLRSRR, where X can be either S or D [44]. However, it was recently shown that there is not an absolute requirement for the RSRR motif to be in its normal sequence context and that primarily appropriate spacing to the plasma membrane is important for its function [45]. The ER retention/retrieval signal in GABA_{B1} is inactivated through interaction with the C-terminus of GABA_{B2}, allowing correctly assembled GABA_{B(1,2)} heterodimers to leave the ER. Structural and mutational analysis identified α helices in the cytoplasmic tails of GABA_{B1} and GABA_{B2}, which were shown to form heterodimeric coiled-coil structure. However, cytoplasmic coiled-coil domain interaction is not an absolute requirement for shielding of the ER retention/retrieval signal in GABA_{B1} and surface trafficking of the heteromeric receptor complex [41]. Recent data suggest a model in which global conformational changes associated with heteromeric assembly remove the ER retention/retrieval signal from

the active zone, thereby restricting its access and triggering surface delivery of the complex [45]. COPI and 14-3-3 are prime candidates for regulating aspects of GABA_B receptor trafficking. COPI components can interact with arginine-based motifs and compete for binding with proteins of the 14-3-3 family [46]. It is thought that 14-3-3 binding overcomes ER retention by preventing recycling of correctly assembled proteins from the ER-Golgi intermediate compartment to the ER via COP1 vesicles [47, 48]. 14-3-3 proteins are known to associate with the C-terminus of

GABA_{B1} through a domain partially overlapping with the coiled-coil domain [49]. It is conceivable that COP1 components bind to RSRR when GABA_{B1} is unassembled, which recycles GABA_{B1} back to the ER. Following heteromeric assembly and removal of the RSRR motif from its active zone, COP1 could then be replaced by 14-3-3, which avoids recycling and allows for surface trafficking. Recently a di-leucine motif in the cytoplasmic tail of GABA_{B1} was identified that is thought to regulate receptor trafficking at the trans-Golgi network (TGN) level through interaction with a guanine-nucleotide exchange factor for the adenosine diphosphate (ADP) ribosylation factor (ARF) family of GTPases [50]. Therefore it was proposed that trafficking of GABA_{B1} subunits is regulated by two distinct motifs within the secretory pathway. Whereas the RSRR motif plays a role in ER retention or the recycling to the ER from the ER-Golgi intermediate compartment, the LL motif could regulate forward trafficking from the TGN to the plasma membrane. A recent study suggested that in addition to GABA_{B2} the γ 2S subunit of the GABA_A receptor can interact with GABA_{B1} and promote its transport to the cell surface [51]. Since GABA_{B2} not only escorts GABA_{B1} to the cell surface but also influences agonist affinity and G-protein coupling (see Section 13.2.6), the resulting GABA_B receptors are expected to differ in their functional and pharmacological properties from the heterodimeric GABA_{B(1,2)} receptors. Of note, it has been shown that GABA_{B2} knockout mice still exhibit electrophysiological GABA_B responses, showing that *in vivo* GABA_{B1} can to some extent overcome ER retention and function in the absence of GABA_{B2} [52]. However, at this point, it cannot be decided whether GABA_B receptors lacking a GABA_{B2} subunit are of physiological relevance or whether they represent an artifact of the knockout situation. Recently, an added level of complexity for the regulation

Figure 13.2 GABA_B receptor structure and subcellular localization. (a) Native GABA_B receptors are heterodimers of two subunits GABA_{B1} and GABA_{B2} (dark blue and pink, respectively). Heterodimerization and cell surface trafficking are facilitated through coiled-coil domain interaction within the cytoplasmic tails. A quality control mechanism involving an ER retention/retrieval signal, the four amino acids RSRR, within the cytoplasmic tail of GABA_{B1} prevents trafficking of unassembled GABA_{B1} to the cell surface. Molecular heterogeneity in the GABA_B system is provided by the GABA_{B1} isoforms GABA_{B1a} and GABA_{B1b}, which are generated by alternative promoter usage. Structurally, GABA_{B1a} differs from GABA_{B1b} by a pair of extracellular sushi repeats, a common protein interaction module. All known GABA_B receptor agonists and competitive antagonists bind to the GABA_{B1} subunits only, whereas G-protein activation is facilitated through the GABA_{B2} subunit. Mutagenesis studies and the lack of evolutionary conservation indicates that the extracellular domain of GABA_{B2} is not the binding site of a natural ligand. Recently, the binding site of the positive allosteric modulator CGP7930 has been localized to the transmembrane domain of GABA_{B2}. (b) In the CNS, GABA_B receptors are localized presynaptically, postsynaptically, and at extrasynaptic sites. Presynaptic GABA_B receptors are subdivided into those that control GABA release (autoreceptors) and those that control the release of other neurotransmitters (e.g., glutamate) and neuropeptides (heteroreceptors). This is achieved by suppressing a Ca²⁺ conductance or by exerting a direct effect on the release machinery (observed in glutamatergic synapses). Postsynaptic GABA_B receptors activate K⁺ channels and induce slow inhibitory postsynaptic potentials (IPSPs), the fast component of which is mediated through GABA_A receptors. Heteroreceptors and extrasynaptic receptors are likely to be activated through “spillover” GABA from adjacent GABAergic synapses. (Modified from [290].) (See color insert.)

of GABA_B receptor assembly and trafficking was suggested by the identification that Marlin-1, a novel RNA binding protein expressed in neurons [53]. Marlin specifically interacts with GABA_{B1} protein but controversially regulates cellular levels of GABA_{B2} in functional experiments.

Integrating these findings it is emerging that interaction of the cytoplasmic tails of GABA_{B1} and GABA_{B2} with each other and with proteins that modulate vesicular transport is crucial for regulating cell surface trafficking of GABA_B receptors. Surprisingly, however, the cytoplasmic tails are dispensable for heterodimerization as such. It was demonstrated that C terminally truncated GABA_{B1} and GABA_{B2} subunits can form fully functional receptors when coexpressed in heterologous cells [41]. This indicates that the transmembrane domains and/or ECDs encode surfaces that are sufficient for heteromerization. This is in agreement with data that suggest that other family 3 GPCRs (e.g., the mGlu1, mGlu5, and CaS receptors) homo-dimerize in their ECDs.

13.2.4 Ligand Binding Site

The discovery of GABA_B receptor heterodimerization triggered a large body of work aimed at defining the structural determinants involved in receptor activation. Similar as in other family 3 GPCRs, ligand binding occurs in the large N-terminal ECD, which is made up of two lobes (I and II) separated by a hinge region. Ligand binding modules of this kind were originally identified in bacterial periplasmic binding proteins, such as the leucine binding protein (LBP). Structural analysis proposed a model where ligand binding in a pocket made up by the two lobes results in their closure, similar to a Venus fly trap when touched by an insect. Extensive mutational analysis of the ECD of GABA_{B1} has demonstrated that residues in both lobes (S246, S269, A471, and E465 in lobe I and Y366 in lobe II) are crucial for agonist and antagonist binding. GABA and baclofen are thought to bind via their carboxylic group to the hydroxyl groups of S246 and Y366. E465 is then believed to bind to the amino terminal end of GABA. D471, which was originally proposed to undergo an ionic interaction with GABA, now appears more important for correct folding of lobe I. Mutation of S247 and Q312 increases the affinity of agonists while decreasing the affinity of antagonists. This supports a model where the LBP-like domain exists in two conformational states, an open and a closed state, where binding of ligands favors the closed state [54]. According to the three-dimensional model, a direct interaction with the second lobe is only possible in the closed form of the LBP-like domain, as shown for other receptors [55, 56]. Some mutations differentially affect the binding of agonists. For example, the potency of GABA is decreased 30-fold by the S269A mutation, whereas the potency of baclofen remains unaltered [57]. This correlates with distinct effects of Ca²⁺ on GABA and baclofen binding [57]. Interestingly, mutation of Y366 in lobe II not only decreases the affinity of GABA and baclofen but also converts baclofen into an antagonist [58]. The recently obtained crystal structure of the dimeric ECD of mGlu1 in the presence and absence of glutamate has essentially validated the homology models for GABA_B subunits described above [59]. Although both GABA_B subunits share the entire bacterial homology domain, *in silico* analysis revealed that the GABA_{B2} lacks the evolutionary constraints placed on the ligand binding pocket of GABA_{B1} or the related

mGluRs [60]. Hence, it is now generally assumed that GABA_{B2} does not bind agonist or antagonist and does not function when expressed alone.

The known activation mechanism of mGlu1 shows that binding of ligand to one of the LBP-like domains induces a conformational change bringing together both LBP-like domains with their proximal lobes. This presumably changes the conformation of the adjacent transmembrane domains, ultimately resulting in signal transduction. The available data suggest that the same mechanism is operational in the heteromeric GABA_B receptors, where binding of single GABA molecules to the LBP-like domain of GABA_{B1} is sufficient for receptor activation. In support of this, elegant experiments by Pin and colleagues demonstrated that closure of the binding domain of GABA_{B1} is sufficient for receptor activation and effector coupling [61]. Connecting the two lobes of the GABA_{B1} LBP-like domain by a disulfide bridge locks the receptor in the closed form in the active state. In agreement with this, GABA_B receptor antagonists, which bind in the open form, are no longer able to inhibit the constitutive activity of the locked receptor.

13.2.5 Molecular Determinants of G-Protein Coupling

Questions were raised as to what domains of the heteromeric GABA_{B(1,2)} complex are involved in the interaction with the G protein and whether two G proteins can bind simultaneously to the receptor. Using chimeric GABA_{B1} and GABA_{B2} subunits with swapped ECDs, it was shown that only the heptahelical region of GABA_{B2} is absolutely necessary for G-protein signaling [62, 63]. However, the heptahelical region of GABA_{B1} significantly improves coupling efficacy. It was later found that all intracellular loops of GABA_{B2} are important for receptor coupling to Kir3 channels, whereas the loops of GABA_{B1} can be replaced with those of GABA_{B2} without affecting function [64–66]. Particular attention was set on addressing the role of the second intracellular (i2) loop since there is evidence that this region is critical for G-protein coupling in family 3 GPCRs [67]. Exchanging the i2 loops between GABA_{B1} and GABA_{B2} did not result in the formation of functional receptors. Hence, the i2 loop of GABA_{B2} needs to be correctly positioned with respect to the other intracellular domains. Sequence comparison between the i2 and i3 loops of GABA_B and the related mGlu receptors highlighted clear differences between GABA_{B1} and GABA_{B2}. Mutational analysis confirmed the functional importance of conserved residues (K586, M587, and K590) in the i2 loop of GABA_{B2} and indicates that the GABA_{B1} i2 loop lacks the requirements for interaction with G proteins [64, 65]. Mutation of K686, a basic residue in the i3 loop of GABA_{B2} that plays a critical role in G-protein coupling of mGlu1 and CaS receptors [68, 69], suppresses functional coupling to G proteins in HEK293 and cerebellar granule cells, corroborating a similar role for this residue [64]. Taken together, these data illustrate the critical role of the heptahelical domain of GABA_{B2} for G-protein activation of the heteromeric GABA_B receptor. This said, one should keep in mind that all data on the importance of the GABA_{B2} subunit for G-protein coupling have been obtained in recombinant expression systems. In vivo, GABA_{B1} is clearly able to couple to G proteins and signal to effector channels in the absence of GABA_{B2} [52]. Information obtained from the crystal structure of rhodopsin and transducin suggests that only a rhodopsin homodimer provides sufficient interface to anchor both G α and G $\beta\gamma$ [70]. Although not generally accepted yet, the data on rhodopsin suggest that all

GPCRs need to homo- or heterodimerize to function. We therefore expect that the GABA_{B(1,2)} heterodimer binds one G protein only — one GABA_B subunit probably interacts with G α while the other subunit interacts with G $\beta\gamma$.

13.2.6 Allosteric Interactions Between Receptor Subunits

As described above, a significant body of work has aimed at defining the structural requirements for ligand binding, subunit interaction, and G-protein coupling. However, the interdependence of heteromerization, surface trafficking, and effector coupling makes it difficult to assign a defined molecular function to structural elements. Nevertheless a number of laboratories reached similar conclusions regarding the sequence of intra- and intermolecular events that take place when activating a GABA_B receptor [44, 62, 65, 71]. A scheme that accommodates most of the available data predicts that the ECD of GABA_{B1} is the only determinant for GABA binding, while the ECD of GABA_{B2} is necessary for receptor activation and increasing agonist affinity. The heptahelical region and the cytoplasmic tail of GABA_{B2} appears to be the prime determinant of G-protein coupling, but GABA_{B1} is clearly necessary to optimize the coupling efficiency. A model was proposed where a conformational change within the dimeric ECDs of GABA_{B1} and GABA_{B2} is responsible for the stabilization of an active dimeric form of the transmembrane domains. Hence, there is an allosteric interaction between the ligand binding domain and the effector transmembrane domains. Since GABA binding to the ECD of GABA_{B1} leads to G-protein activation by the GABA_{B2} heptahelical domain, this mechanism is also referred to as trans-activation (for a recent review see [6]). It is assumed that the GABA_B heterodimer differs from the homodimers formed by other family 3 GPCRs with respect to the functional coupling between binding and effector domains. In the GABA_B receptor the conformations of the effector and binding domains are probably tightly coupled, that is, the two domains are both in either an active or inactive conformation [71]. This model is reminiscent of a two-state model for receptor activation.

13.3 EFFECTOR SYSTEMS

13.3.1 G-Protein-Dependent and G-Protein-Independent GABA_B Effects

The best known synaptic effects of GABA_B receptors — presynaptic block of neurotransmitter release and postsynaptic hyperpolarization — are fast and mainly due to the inhibition and activation of Ca²⁺ and K⁺ channels, respectively. These effects are mediated through the $\beta\gamma$ subunits of the activated G proteins in a membrane-delimited manner not requiring any signaling through second-messenger cascades. In addition, GABA_B receptors also signal through the α subunits of the activated G proteins, which inhibits adenylate cyclase and, for example, retards the recruitment of synaptic vesicles during sustained activity and after short-term depression [72]. Moreover, GABA_B receptors regulate mitogen-activated protein kinases (MAPKs) and other cytoplasmic kinases. GABA_B signaling through second-messenger systems is generally slower and the physiological consequences are largely unknown. However, it is emerging that coupling of GABA_B receptors to intracellular

signaling cascades influences transcription, translation, stability, and activity of protein and is involved in the modulation of synaptic plasticity.

The G-protein-dependent effects of GABA_B receptor activation are largely mediated by G proteins that are members of the pertussis toxin-sensitive family G α_i /G α_o , which negatively regulate adenylate cyclase and do not couple to phospholipase C (PLC) [73, 74]. However, coupling to pertussis toxin-insensitive G proteins has been observed occasionally [75]. Moreover, recent work by Hirono and colleagues suggests that GABA_B receptors also couple to PLC in a G α_i /G α_o -linked manner resulting in the facilitation of mGlu1 responses at excitatory synapses in the cerebellum [76]. It is thought that this involves a cooperative upregulation of GPCR signaling by the G $\beta\gamma$ subunits. This is reminiscent of synergistic interactions seen with GABA_B and β -adrenergic receptors [77].

13.3.2 Ca²⁺ Channels

Presynaptic GABA_B receptors are subdivided into those that control GABA release (autoreceptors) and those that inhibit all other neurotransmitter release (heteroreceptors). In most preparations GABA_B receptors mediate their presynaptic effects through a voltage-dependent inhibition of high-voltage activated Ca²⁺ channels of the N type (Ca_v2.1) or P/Q type (Ca_v2.2/3) [78–86]. Both types of Ca²⁺ channels are expressed in presynaptic terminals and were shown to trigger neurotransmitter release [87]. A postsynaptic inhibition of Ca²⁺ channels was also postulated [88]. It was shown that GABA_B receptors couple to different types of Ca²⁺ channels depending on the input site [89]. The inhibition of Ca²⁺-inward currents is voltage dependent and varies between 10 and 42% among studies [90–92]. Since Ca²⁺ influx and transmitter release are correlated with a third- to fourth-power law [87], GABA_B agonists frequently inhibit more than 90% of neurotransmitter release with a less than 50% inhibition of Ca²⁺ channel activity. This inhibition is modulated by the action potential frequency, where strong depolarization relieves Ca²⁺ channels from their G $\beta\gamma$ -mediated inhibition [93–95]. This particular property of presynaptic Ca²⁺ channels may differentially modulate action potential trains, depending on their frequency [96]. GABA_B receptors are also described to either inhibit [81, 97, 98] or facilitate [99] L type Ca²⁺ channels. The latter effect was shown to be indirect and depend on protein kinase C (PKC) activity. Similarly, GABA_B receptors also inhibit or disinhibit T type Ca²⁺ channels [100–104]. GABA_B autoreceptors are thought to be activated only after synchronized GABA release from multiple inhibitory terminals, possibly indicating a remote localization from the synaptic cleft [105–107]. In this context it is interesting to note that it proved difficult to demonstrate presynaptic GABA_B receptors on inhibitory terminals by immunohistochemical methods, suggesting that receptor protein levels are fairly low. However, when detected, they are mostly localized to the extrasynaptic membranes [13, 108, 109]. Once activated by GABA release there is a delay of 20–50 ms prior to initiation of inhibition. Maximum inhibition then occurs after 100–200 ms and lasts up to 5 ms [110–116]. GABA_B heteroreceptors are more diverse than GABA_B autoreceptors in that they control the release of numerous neurotransmitters, including glutamate, monoamines, and many neuropeptides [1, 78–86, 117–119]. It was suggested that GABA_B heteroreceptors inhibit glutamate release via a direct inhibition of the release machinery rather than inhibiting Ca²⁺ influx [72, 120]. Heteroreceptors on

glutamatergic terminals, like GABA_B autoreceptors, are mostly localized on the extrasynaptic membrane. Activation of GABA_B heteroreceptors is thought to require a spillover of GABA from highly active GABAergic terminals. Once activated, the time course of GABA_B-induced inhibition of glutamate release is very similar to the autoreceptor-mediated inhibition of GABA.

13.3.3 K⁺ Channels

Postsynaptic GABA_B receptors induce a slow inhibitory postsynaptic current (late IPSC) through activation of inwardly rectifying K⁺ channels (GIRK or Kir3) [121, 122]. Accordingly, GABA_B-induced late IPSCs can be inhibited by the Kir3 channel blocker Ba²⁺ [123–125] and they usually exhibit a reversal potential similar to the K⁺ equilibrium potential [126, 127]. The physiological effect of Kir3 channel activation is normally a K⁺ efflux, resulting in a hyperpolarization. The time course of the late IPSC, with a time to peak of 50–250 ms and decay times of 100 and 500 ms, clearly differs from that of the fast IPSC, which is GABA_A receptor mediated [127, 128]. Baclofen-induced outward currents in hippocampal neurons are absent in *Kir3.2*, *GABA_{B1}*, and *GABA_{B2}* knockout mice, corroborating the prominent role of Kir3 channels in mediating the effects of GABA_B receptors [52, 121, 122]. Application of baclofen in the ventral tegmental area induces desensitizing and nondesensitizing Kir3 currents in dopaminergic and GABAergic neurons, respectively [129]. The difference in desensitization properties was attributed to differences in the effector Kir3 channels. The rectification properties of synaptically evoked late IPSCs differed between studies. On the one hand, the stimulus-evoked and spontaneous late IPSCs in dopaminergic neurons are inwardly rectifying and similar to those activated by baclofen [130]. On the other hand, baclofen also induces linear or even outwardly rectifying conductances, suggesting that channels other than Kir3 can contribute to the late IPSC. These other channels may include fast-inactivating, voltage-gated K⁺ channels [131] and small-conductance Ca²⁺-activated K⁺ channels (SK channels) [132]. Accordingly, the fast-inactivating A type K⁺ channel blocker 4-aminopyridine inhibits a baclofen-induced current in guinea pig hippocampal neurons [133, 134]. Moreover, GABA activates Ca²⁺-sensitive K⁺ channels [135] and small-conductance K⁺ channels [135, 136] in rat hippocampal neurons. Possibly, GABA_B receptors enhance the activity of SK channels by inhibiting the production of cyclic adenosine monophosphate (cAMP) after an action potential-induced Ca²⁺ influx [132]. Besides the well-documented coupling of GABA_B receptors to postsynaptic K⁺ channels, GABA_B receptors also appear to activate Ba²⁺-sensitive K⁺ channels at presynaptic sites [125]. Likely these presynaptic K⁺ channels are of the Kir3 type, devoid of the Kir3.2 subunit and assembled from Kir3.1 and Kir3.4 subunits [121].

13.3.4 Adenylate Cyclase

All of the known nine adenylate cyclase isoforms are expressed in neuronal tissue. Gα_i and Gα_o proteins, the predominant transducers of GABA_B receptors, inhibit most of them [137]. Many studies have reported that GABA_B receptors inhibit forskolin-stimulated cAMP formation, but others also observed a stimulation of cAMP production [138, 139]. Gα_i and Gα_o proteins inhibit adenylate cyclase types I, III, V, and VI, while Gβγ stimulates adenylate cyclase types II, IV, and VII. This

stimulation depends on the presence of $G\alpha_s$, which results from the activation of GPCRs by, for example, noradrenaline, isoprenaline, histamine, or vasoactive intestinal polypeptide [137, 140]. Therefore, the stimulatory action of $GABA_B$ receptors on cAMP levels is a consequence of G-protein crosstalk and depends on the expression of adenylate cyclase isoforms together with $GABA_B$ and $G\alpha_s$ -coupled GPCRs. Both the inhibition and enhancement of cAMP levels by $GABA_B$ receptor activation were confirmed in vivo using microdialysis [141]. Many ion channels are targets of the cAMP-dependent kinase (protein kinase A, or PKA). Accordingly, $GABA_B$ receptors can change the phosphorylation state of these proteins by influencing intracellular cAMP levels. For example, $GABA_B$ receptors increase the activity of P2X type adenosine triphosphate (ATP) receptors or the calcium-dependent K^+ current (IAHP) through a downregulation of cAMP levels, resulting in decreased PKA activity and subsequent dephosphorylation of the ion channel [132, 142]. Possibly the interplay between the GABA and ATP neurotransmitter systems could be exploited for the treatment of neuropathic pain. Significantly, the activity of $GABA_B$ receptors on adenylate cyclase is expected to modulate neuronal function on a longer time scale.

$GABA_B$ receptors were repeatedly implicated in synaptic plasticity [143–148]. Until recently it was unclear whether $GABA_B$ receptors can influence plasticity processes through the cAMP pathway. Recent experiments now demonstrate that G-protein-mediated signaling through $GABA_B$ receptors retards the recruitment of synaptic vesicles during sustained activity and after short-term depression [72]. This retardation occurs through a lowering of cAMP, which blocks the stimulatory effect of the increased Ca^{2+} concentration on vesicle recruitment. In this signaling pathway, cAMP and Ca^{2+} /calmodulin cooperate to enhance vesicle priming.

13.3.5 MAPK

MAPKs play a key role in the regulation of cellular processes. Until recently this signal transduction pathway had largely been investigated for its role in regulating cell division and differentiation in nonneuronal cells. It is emerging that MAPKs are abundantly expressed in the CNS and that in particular extracellular signal-regulated kinases (ERKs) are involved in neuronal plasticity and memory consolidation [149]. Given the role of ERK cascade in transcriptionally regulated processes, initial ERK studies focused on long-term forms of synaptic plasticity. More recent studies, however, implicate the ERKs in forms of synaptic plasticity that do not require macromolecular synthesis, such as the modulation of ion channel activity or the trafficking and insertion of α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors at central synapses [150–154]. There are conflicting results on the coupling of $GABA_B$ receptors to MAPKs. It was shown that $GABA_B$ receptors can activate or inhibit ERKs [155, 156]. This discrepancy could either relate to differences in the experimental conditions or reflect that there are multiple ways for $GABA_B$ receptors to couple to MAPKs in neurons. There could be significant crosstalk between $GABA_B$ signaling pathways. For example, it is tempting to speculate that $GABA_B$ receptors couple to MAPKs through the modulation of cAMP levels and PKA. It will be interesting to see whether $GABA_B$ receptor coupling to MAPKs is important for mediating some of the $GABA_B$ effects on synaptic plasticity.

13.4 GABA_B RECEPTOR MODULATION

13.4.1 Extracellular Calcium

In addition to intra- and intermolecular interactions involved in the activation of the heteromeric GABA_B receptor, modulation can also occur via allosteric interactions with endogenous ligands as well as exogenous compounds. Investigating a possible regulation of GABA_B receptors by Ca²⁺ led to the identification of a Ca²⁺ binding site in the GABA_{B1} subunit as the first allosteric site of GABA_B receptors [57, 157]. Accordingly, it was shown that Ca²⁺ potentiates GABA-stimulated GTPγ[³⁵S] binding in membranes expressing native or recombinant GABA_B receptors. The effect of Ca²⁺ depends on the agonist, with baclofen being less sensitive than GABA or 3-aminopropyl-phosphinic acid (3-APPA). The residues that confer to GABA_B receptors the ability to sense Ca²⁺ were identified [57]. The S269A mutation in the LBP-like domain of GABA_{B1} renders the otherwise functional GABA_{B(1,2)} receptor Ca²⁺ insensitive. S269 localizes to the GABA binding pocket, next to S246 that interacts with agonists [58]. S269 in GABA_{B1} aligns with S170 in the CaS receptor, a residue that is involved in Ca²⁺ activation of the CaS receptor [158]. Allosteric regulation of GABA_{B1} by Ca²⁺ is supposed to stabilize the activated closed conformational state [57]. Possibly, Ca²⁺ compensates for the lack of the α-amino group in GABA and the contact of Ca²⁺ with S269 optimizes positioning of the carboxylic group of GABA for contacting S246. Alternatively Ca²⁺ does not directly interact with S269 but affects the positioning of its hydroxyl group. This may allow the formation of an additional hydrogen bond with the carboxylic group of GABA. The median effective concentration (EC₅₀) for Ca²⁺ modulation of GABA binding at GABA_B receptors is with 37 μM rather low. Under normal physiological conditions, with [Ca²⁺] in the blood and cerebrospinal fluid in the millimolar range, the Ca²⁺ site of GABA_B receptors is saturated. Allosteric regulation by Ca²⁺ may, however, become significant under pathological conditions, when extracellular [Ca²⁺] is low. This could be the case following ischemia [159] or epileptic seizures [160]. Recently, a GABA-independent role for the Ca²⁺-sensing property of GABA_B receptors was suggested. In cerebellar Purkinje cells, interaction of GABA_B receptors with extracellular Ca²⁺ leads to a constitutive increase in glutamate sensitivity of mGlu1 [161]. This constitutive sensitization at physiological Ca²⁺ concentrations may serve a different purpose than the transient enhancement of mGlu1 signaling by GABA_B receptor activation previously reported [76].

13.4.2 Phosphorylation and Receptor Desensitization

Modulation of GPCR activity by intracellular kinases is well known and usually the trigger for activity-dependent desensitization [162]. In general, phosphorylation of the receptor protein is followed by interaction with cytoplasmic accessory proteins called β-arrestins, which interfere with receptor–G protein coupling and promote rapid endocytosis. Both GABA_{B1} and GABA_{B2} cytoplasmic tails contain a number of consensus sites for PKC and/or PKA. Moreover, PKC is reported to suppress GABA_B-mediated inhibition of neurotransmitter release [163]. Similarly, PKA is described to desensitize GABA_B receptors expressed in *Xenopus* oocytes [164]. Subsequently, it was observed that PKC- and PKA-dependent signaling pathways

mediate the modulation of GABA_B activity in response to estrogen [165, 166]. Agonist-induced desensitization and endocytosis of heterodimeric GABA_B receptors were also observed in heterologous CHO cells [167]. However, other molecular studies contrast these findings. Moss and colleagues reported that PKA phosphorylation of S892 in the cytoplasmic tail of GABA_{B2} reduces rather than increases receptor desensitization, probably as a result of stabilizing the receptor complex at the cell surface [168]. This serine residue, at position 892 in rat and mouse GABA_{B2} is at position 893 in human GABA_{B2} due to the insertion of an additional proline residue in the signal peptide (see GenBank accession number AF099033). To simplify matters, we continued referring to it as S892 throughout the text. The data of Couve et al. challenge the conventional view that phosphorylation is a negative modulator of GPCR signaling. S892 phosphorylation in GABA_{B2} was also observed in another experimental paradigm [169]. It was shown that withdrawal from repeated cocaine treatment produces an increase in the basal level of extracellular GABA in the rat accumbens. The increase in extracellular GABA is paralleled by diminished S892 phosphorylation, suggesting a functional desensitization of GABA_B autoreceptors. At first glance contradictory, Bouvier and colleagues identified the GPCR kinase 4 (GRK4) as the kinase that promotes desensitization of GABA_B receptors [170]. Surprisingly, however, this desensitization occurred in the absence of ligand-induced receptor phosphorylation and could be promoted by GRK4 mutants deleted of their kinase domain. Again, these results are at odds with the generally accepted model linking the kinase activity of GRKs to their role in receptor desensitization. To date it is still unclear whether receptor internalization, ligand dependent or independent, is involved in the desensitization to repeated or prolonged application of GABA_B receptor agonists [171]. Recent data obtained in animal models have shown that even after prolonged baclofen application the total protein and messenger ribonucleic acid (mRNA) levels for GABA_{B1} and GABA_{B2} remained unchanged [172, 173]. It also remains to be addressed whether the clinically important development of tolerance to baclofen application is related to receptor phosphorylation or not. Identification of a potential proline-directed kinase target site in the cytoplasmic tail of GABA_{B2} (S884) by phosphoproteomic analysis of synaptosomes prepared from human cerebral cortex suggests the involvement of multiple signal transduction pathways in the regulation of GABA_B receptors [174].

13.4.3 Interacting Proteins

The discovery that receptor activity modifying proteins (RAMPs) can change the pharmacology of a GPCR triggered an intense search for proteins interacting with GABA_B receptors [175]. It was speculated that the pharmacological differences that were observed between pre- and postsynaptic GABA_B receptors relate to receptor-associated proteins that differentially interact with specific receptor populations. A number of candidate proteins were identified in yeast two-hybrid screens using the C-terminal domains of GABA_{B1} or GABA_{B2} as baits. However, there are no reports claiming pharmacological changes upon expression of these proteins together with GABA_{B1}, GABA_{B2}, or heteromeric GABA_{B(1,2)}.

Three laboratories described that the C-terminal domain of GABA_{B1} interacts with members of the ATF/CREB family of transcription factors, that is, ATF4/CREB2 and ATFx [176–178]. Gadd153, also known as CHOP, is an additional

leucine-zipper transcription factor that was described to bind to GABA_B receptors [179]. These findings are both intriguing and provocative, as they suggest a direct interaction between a GPCR and transcription factors. In addition, stimulation of GABA_B receptors resulted in transcriptional activation of ATF4/CREB2-responsive reporter genes [176, 177]. Paradoxically, in one case pertussis toxin blocked transcriptional activation, whereas in the other case pertussis toxin was ineffective. GABA_B signaling through CREB proteins was already proposed prior to cloning [180, 181]. In these earlier studies baclofen silenced transcription instead of activating it. These earlier findings are more in agreement with the well-known inhibitory effect of baclofen on cAMP production. Nerve growth factor (NGF) and brain-derived neurotrophic factor (BDNF) genes may well be the targets of GABA_B-mediated transcriptional regulation. Both the production of NGF and BDNF are stimulated after treatment of rats with GABA_B receptor antagonists [182]. Taken together, the data suggest a novel and unique mechanism of signal transduction to the nucleus that results from activation of GABA_B receptors. Although still conflicting, the data linking GABA_B receptors to transcription factors suggest that these receptors mediate long-term metabolic effects requiring new protein synthesis. Intriguingly, a selective control of alternative GABA_{B1a} and GABA_{B1b} promoters by CREB, ATF4, and the depolarization-sensitive upstream stimulatory factor (USF) was reported [19], proposing a feedback loop regulating GABA_B isoform expression.

The intracellular C-terminus of GABA_{B1} associates with a number of proteins that are thought to regulate GABA_{B(1,2)} heteromerization and/or cell surface delivery. These include two members of the 14-3-3 family of signaling proteins [49], Marlin-1, a novel RNA binding protein [53], and msec7-1, a guanine-nucleotide exchange factor for the ARF family of GTPases [50]. Their suggested role in the assembly of functional GABA_B receptor is discussed in Section 13.2.3. The 14-3-3 proteins were implicated in GPCR signaling before [183, 184]. For example, they directly influence G-protein coupling efficiency and act as scaffolds that recruit proteins modulating G-protein activity, such as protein kinases and regulators of G-protein signaling (RGS). In addition, owing to their dimeric nature, 14-3-3 proteins might be directly implicated in the clustering of GABA_B receptors at pre- or postsynaptic sites. There are additional scaffolding proteins that interact with GABA_B receptors. *N*-Ethylmaleimide-sensitive factor, or NSF, an ATPase critical for intracellular trafficking, interacts with the C-terminus of GABA_{B2} [185]. NSF also interacts with GABA_A receptors through its binding of GABARAP [186] and possibly provides a structural link between the ionotropic and metabotropic GABA receptor systems. Tamalin is yet another scaffolding protein that interacts with GABA_B as well as mGlu receptors [187]. Tamalin is also proposed to interact with guanine-nucleotide exchange factor cytohesins and to promote intracellular trafficking and cell surface expression of associated receptors. Tamalin comprises multiple protein-interacting domains, including a 95-kDa postsynaptic density protein (PSD-95)/discs-large/ZO-1 (PDZ) domain [188], a leucine-zipper regions and a carboxy-terminal PDZ-binding motif. PDZ domain proteins are important for the scaffolding of receptors at synapses and in epithelia [189]. MUPP1, a multivalent PDZ protein, interacts with a stretch of 10 amino acids proximal to the coiled-coil domain of GABA_{B2} [4]. Interestingly this sequence does not conform to the PDZ domain binding consensus sequence. MUPP1 was initially shown to interact with another GPCR, the 5-HT_{2c} receptor [190]. MUPP1 may serve as an adaptor protein linking

GABA_{B2} to various signaling molecules. Intriguingly the GABA_{B1} C-terminus contains a putative PDZ domain binding consensus sequence, LYK. However, no PDZ domain protein is reported to interact with GABA_{B1}. Finally, the actin binding protein β -filamin is proposed to tether GABA_B receptors via the GABA_{B2} subunit to the cytoskeleton [185].

Two reports suggest that GABA_B receptor ECDs interact with other proteins. Fibulin, an extracellular matrix protein, apparently binds to the sushi repeats of the GABA_{B1a} subunit [20]. This finding is of special interest, as we still do not know whether mechanisms are in place to compartmentalize GABA_{B1a} and GABA_{B1b} to different subcellular regions, for example, pre- and postsynaptic sites. The other report provides evidence that the HNK-1 carbohydrate carried by many neural extracellular matrix proteins, among them tenascin-R and tenascin-C, binds to GABA_B receptors [191]. HNK-1 was proposed to regulate GABA_A receptor-mediated perisomatic inhibition by suppression of postsynaptic GABA_B receptor activity. HNK-1 does not bind to the sushi repeats of GABA_{B1a}.

GABA_B receptors were found to be associated with lipid rafts, specialized plasma membrane microdomains that function as platforms for signaling complexes [192]. Lipid rafts are enriched in cholesterol/sphingolipids and contain specific populations of membrane-associated proteins, such as G-proteins and other signaling molecules. For example, G α_i - and G α_o -type G proteins, the main transducers of GABA_B receptors, are enriched in the lipid-raft fraction extracted from cerebellar membranes. It remains to be seen whether lipid rafts can segregate GABA_B receptor populations (e.g., GABA_{B(1a,2)}} and GABA_{B(1b,2)}}), and in some ways account for the functional heterogeneity observed in vivo.

13.5 GABA_B-DEFICIENT MICE

Given that cloning efforts did not substantiate the claim for receptor heterogeneity, it became important to understand to which GABA_B functions the cloned receptors can contribute in vivo. To address this question, a number of laboratories generated knockout mice lacking either GABA_{B1} [122, 193, 194] or GABA_{B2} [52, 195]. Only the GABA_B knockout mice generated on the Balb/c genetic background are viable [52, 122]. The GABA_B knockout mice generated on other genetic backgrounds die within three to four weeks after birth, thus precluding behavioral analysis of adult animals [193–195]. Strain differences in viability of knockout mice are not uncommon [196]. The overt phenotype of all GABA_B-deficient mice includes spontaneous epileptic seizures and these seizures may be suppressed to some extent in the Balb/c genetic background. A reduced seizure activity, in turn, may rescue mice from lethality. Analysis of GABA_{B1}^{-/-} and GABA_{B2}^{-/-} mice revealed that deletion of either subunit is sufficient to abolish all well-known GABA_B responses. Upon GABA_B agonist application, GABA_{B1}^{-/-} and GABA_{B2}^{-/-} mice show neither the typical muscle relaxation and hypothermia nor delta EEG waves. These behavioral findings are paralleled by a loss of all detectable biochemical and typical pre- and post-synaptic electrophysiological GABA_B responses. However, whereas GABA_B-mediated responses are completely lacking in GABA_{B1} knockout mice, an atypical response is observed in GABA_{B2}-deficient mice [52]. In CA1 hippocampal neurons baclofen inhibits instead of activates K⁺ channels. Whether a physiological relevant

signaling underlies these atypical GABA_B responses in GABA_{B2}^{-/-} mice is unclear. It is possible that these responses are a consequence of the knockout situation where GABA_{B1} is expressed in the absence of its usual dimerization partner. These findings substantiate that all classical GABA_B responses in vivo relate to heteromeric GABA_{B(1,2)} receptors. The heteromeric nature of predominant native GABA_B receptors is further emphasized by the substantial down regulation of GABA_{B2} protein in GABA_{B1}^{-/-} mice and vice versa. In conclusion, knockout studies demonstrate that GABA_{B1} as well as GABA_{B2} are essential components of abundant pre- and postsynaptic GABA_B receptors in the CNS. Analysis of GABA_{B1}^{-/-} mice further indicates that the GABA_{B1} subunit is an essential requirement for GABA_B receptor function in the peripheral nervous system and the enteric nervous system [197]. Therefore, gene-targeting experiments do not substantiate the existence of GABA_B subtypes in the periphery, claimed by studies in which different rank orders of GABA_B agonist affinities were reported.

Theoretically, it remains possible that additional GABA_B subunits exist, which could explain the discrepancy between the historically diverse receptor pharmacology in vivo on the one hand and the lack of pharmacologically distinct cloned receptors on the other hand. However, with most of the human genome sequence available, and despite extensive data-mining efforts, no GABA_B genes other than *GABA_{B1}* and *GABA_{B2}* were identified. All GABA_B-related proteins that were isolated do not form functional GABA_B receptors when expressed together with GABA_{B1} and/or GABA_{B2} [198–203]. Altogether, this indicates that the likelihood of identifying additional GABA_B receptor genes in the future is small.

13.6 PHARMACOLOGY

13.6.1 Endogenous GABA_B Ligands: GABA and GHB

Over the past decade it was emerging that GABA is not the only endogenous GABA_B ligand. It is now generally accepted that GHB, a metabolite of GABA that is present at micromolar concentration in the brain, interacts with GABA_B receptors [156, 204–206]. Patients suffering from GHB aciduria, a congenital enzyme defect causing a GHB accumulation, exhibit psychomotor retardation, delayed or absent speech, hypotonia, ataxia, hyporeflexia, seizures, and EEG abnormalities. GHB binds to native and recombinant GABA_B receptors, however with significantly lower affinity than to its cognate high-affinity [³H]GHB binding sites [206]. Therefore, GHB is only expected to activate GABA_B receptors when endogenous GHB levels increase above physiological levels, due either to a genetic disease or to exogenous administration of GHB (see below). The physiological role of endogenous GHB is unclear. However, if endogenous GHB is involved in active signaling, high-affinity GHB receptors, likely related to brain [³H]GHB binding sites, are expected to mediate these effects. The availability of GABA_B-deficient mice provided the opportunity to study GHB effects in the absence of coincident GABA_B effects [194, 207, 208]. Following GHB application, GABA_{B1}^{-/-} mice did not show the typical hypolocomotion, hypothermia, increase in striatal dopamine synthesis, or EEG delta-wave induction seen in wild-type mice. This indicates that these GHB effects are all mediated by GABA_B receptors. Autoradiography reveals a similar spatial

distribution of [^3H]GHB binding sites in brains of $\text{GABA}_{\text{B1}}^{-/-}$ and wild-type mice, demonstrating that GABA_{B} subunits are not part of high-affinity [^3H]GHB binding sites. Millimolar concentrations of GHB induce small $\text{GTP}\gamma[^{35}\text{S}]$ responses in brain membrane preparations from wild-type but not from $\text{GABA}_{\text{B1}}^{-/-}$ mice. The $\text{GTP}\gamma[^{35}\text{S}]$ responses in wild-type mice are blocked by the GABA_{B} antagonist CGP54626, but not by the GHB antagonist NCS-382. This, together with additional data [209], suggests that the GHB-induced $\text{GTP}\gamma[^{35}\text{S}]$ responses are exclusively mediated by GABA_{B} receptors and not by the high-affinity [^3H]GHB binding sites, as proposed in earlier studies [210, 211].

Recently, the cloning of a putative GHB receptor from a rat hippocampal cDNA library was reported [212]. However, several findings related to this putative GHB receptor require clarification. For example, the N-terminal part of the cloned GHB receptor identifies it as a member of the tetraspannin gene family, with four transmembrane regions and no significant similarity to GPCRs. Nevertheless, the cloned protein is reported to exhibit seven transmembrane regions and to activate G proteins. No additional transmembrane domains to achieve the typical GPCR topology are visible in the C-terminal part of the protein, which exhibits no significant homology to known proteins. All the more puzzling, the mRNA of the putative GHB receptor is particularly abundant in the cerebellum, where GHB binding sites are low or absent [204]. Furthermore, the GHB receptor antagonist NCS-382 has no activity at the cloned GHB protein. In summary, these findings make it unlikely that the cloned protein corresponds to the high-affinity [^3H]GHB binding sites in the brain.

In the past GHB was clinically used as an anesthetic, while in recent times it is shown to normalize sleep patterns in narcoleptic patients [213, 214]. GHB (Xyrem) is used to reduce the number of cataplexy attacks in patients with narcolepsy [215]. Preliminary preclinical and clinical data suggest that GHB is also useful in the therapy of alcoholism, nicotine, and opiate dependency [216], similar to baclofen. However, in contrast to baclofen, GHB is recognized as a drug with a strong abuse potential itself [214] (see Section 13.7.2).

13.6.2 Agonists and Competitive Antagonists

13.6.2.1 Agonists. The prototypic GABA_{B} agonist β -[4 chlorophenyl] GABA (baclofen, Lioresal) was synthesized in 1962 and introduced to the market as an antispastic agent in 1972 [217]. Thus baclofen was in clinical use long before GABA_{B} receptors were identified as a distinct entity [1]. Since then 3-APPA (CGP27492) and its methyl homolog (3-APMPA, CGP35024, identical with SK&F 97541) have emerged and are reported to be three-to seven fold more potent than the active isomer of baclofen. The latter compounds are also available as radioligands. Other methyl phosphinic acid-based agonists have been produced, such as CGP44532 and its (R)-(+)-enantiomer CGP44533. Interestingly, ethyl (and higher homolog) phosphinic acid derivatives (e.g., CGP36216) are GABA_{B} antagonists [218]. The difluoromethyl phosphinic acid derivative CGP47656, with a substituent the size of which is between a methyl and an ethyl group, showed properties of a partial GABA_{B} agonist [219]. GABA_{B} receptor agonists display a great number of pharmacological effects, including central muscle relaxation, antinociception, epileptogenesis, and suppression of cocaine and nicotine/opioid self-administration. As mentioned above, GHB (Xyrem) has been recently introduced to the market [215]. GHB is a partial

agonist at GABA_B receptors [206]. Since no physiological responses of GHB are observed in GABA_B knockout mice [194, 207], it is likely that the therapeutic effects of Xyrem are due to activation of GABA_B receptors.

13.6.2.2 Antagonists. Kerr and colleagues synthesized the first GABA_B antagonists, phaclofen and 2-hydroxy saclofen [220, 221]. Both compounds exhibit only low micromolar affinities for brain GABA_B sites but were instrumental in advancing our understanding of GABA_B receptor function. Subsequently, the first antagonists that cross the blood–brain barrier after intraperitoneal (CGP35348) or oral administration (CGP36742) were synthesized [144, 147]. Bolser and colleagues reported SCH50911, a structurally distinct GABA_B antagonist that also acts centrally after peripheral administration [222]. Nonetheless all these later compounds suffered from low potency. A breakthrough was the development of the phosphinic acid derivatives CGP52432, CGP55845A, CGP54626A, CGP56433A, CGP61334, and CGP62349. These antagonists now reached nanomolar affinities at GABA_B receptors [218, 223]. Subsequently several high-affinity radioligands were developed which ultimately permitted expression cloning of the first GABA_B receptor cDNA [3] (see Section 13.2.1). Like GABA_B agonists, GABA_B antagonists exert a great number of physiological effects. For instance, they suppress absence seizures in various rodent models or improve cognitive performance in a variety of learning paradigms (see Section 13.7).

Using the above-described GABA_B compounds numerous biochemical and physiological studies postulate pharmacological differences between auto- and heteroreceptors and even within auto- and heteroreceptors [119, 224–228]. However, the proposal of presynaptic receptor subtypes based on neurotransmitter release experiments has been open to dispute [229]. Electrophysiological and release experiments suggest distinctions between pre- and postsynaptic GABA_B receptors as well [125, 230–238]. Accordingly, published half-maximal effective concentrations for baclofen in pharmacological studies vary considerably and range between 500 nM and 15 μ M.

The rank order of agonist and antagonist binding affinities at GABA_{B1} and native GABA_B receptors is identical [3]. This, together with the reasons outlined in Sections 13.2.2, 13.5, and 13.6.3.2, makes it unlikely that molecularly distinct GABA_B receptor subtypes or isoforms underlie these pharmacological differences. Obviously, the ratio of receptors and effectors can determine the apparent potency of receptor agonists [239]. Agonist potency may also depend on the concentration of divalent cations in the extracellular buffer, the association with lipid rafts [192], the phosphorylation state of subunits, or the type of G protein that is present in the cell. These factors may also explain why the agonist affinity at GABA_B receptors increases 10-fold during postnatal development [22]. This said, all experiments with native GABA_B receptors reporting changes in the rank order of ligand efficacies remain unexplained [224, 231]. These experiments would normally clearly argue in favor of pharmacologically distinct receptor subtypes.

13.6.3 Novel GABA_B Compounds

13.6.3.1 Allosteric Modulators. The side effects of baclofen, principally sedation, tolerance, and motor impairment, limit its utility for the treatment of many diseases.

Novel GABA_B drugs that largely lack these components are therefore much sought after. In the absence of pharmacological subtypes, alternative strategies for achieving selectivity must be considered. For instance, positive allosteric modulators may provide a means to dissociate the unwanted side effects seen with baclofen. Allosteric modulators discriminate between activated and nonactivated receptor states. They will enhance the endogenous activity of GABA, in contrast to agonists that will activate every GABA_B receptor they reach, independently of synaptic activity. To be effective, allosteric GABA_B drugs therefore rely on receptor activity stimulated by endogenous GABA. The demonstration of an intrinsic brake on memory impairment, locomotion, bladder activity, and nociception in GABA_{B1}^{-/-} and GABA_{B2}^{-/-} mice [52, 122, 197] is therefore of great importance (Section 13.5). This suggests that under physiological conditions disease-relevant neuronal systems are under phasic or tonic control of GABA_B receptors and that a treatment with allosteric modulators is possible.

Using cloned GABA_B receptors, several laboratories developed functional assay systems. For instance, the activation of G proteins by GABA_{B(1,2)} can be measured using the GTPγ[³⁵S] binding assay [240]. Alternatively mobilization of intracellular Ca²⁺ can be detected in cell lines expressing GABA_{B(1,2)} in combination with chimeric G proteins [41]. Functional assay systems permitted the identification of the first synthetic allosteric GABA_B compounds [240, 241]. CGP7930, CGP13501, GS39783 and related allosteric compounds are structurally distinct from GABA_B agonists and markedly enhance agonist-stimulated responses at GABA_B receptors (Fig. 13.3). Notably, these allosteric compounds have little or no intrinsic activity and do not directly activate GABA_B receptors [242]. Where analyzed, GABA concentration–response curves in the presence of fixed concentrations of the allosteric modulator indicate an increase of both the potency and the maximum efficacy of GABA at GABA_{B(1,2)} receptors. The published allosteric compounds do not discriminate between GABA_{B(1a,2)} and GABA_{B(1b,2)}, the two predominant GABA_B receptor populations in the nervous system. The precise binding sites for allosteric modulators are unknown, but all compounds require the presence of GABA_{B2} to exert their allosteric effect. Possibly, the compounds bind to the GABA_{B2} subunit itself or to the GABA_{B1}/GABA_{B2} interface. Indeed, using interspecies rat/*Drosophila* subunit combinations, it was recently shown that the positive modulator GS39783 binds to the GABA_{B2} subunit [243]. Moreover, it is suggested that CGP7930 directly

Figure 13.3 Positive allosteric modulators acting at GABAB receptors. Chemical structures described by Urwyler et al. [240, 241]. CGP7930 [2,6-di-*tert*-butyl-4-(3-hydroxy-2,2-dimethylpropyl)-phenol], its aldehyde analog CGP13501, and GS39783 [*N,N'*-dicyclopentyl-2-methylsulfanyl-5-nitro-pyrimidine-4,6-diamine] are shown.

acts on the transmembrane domain of GABA_{B2} [244]. Therefore it is conceivable that all these hydrophobic compounds interact with the transmembrane domains, similar to allosteric modulators at mGlu receptors (see below). Kerr and colleagues [245] described the arylalkylamines as a different class of positive allosteric GABA_B modulators. However, this is not supported by subsequent experiments in another laboratory [246].

Positive allosteric modulation is not the sole possibility to fine tune GABA_B receptors. High-throughput screening using functional read-outs allows identification of noncompetitive GABA_B antagonists as well. This has been demonstrated for the structurally related mGlu receptors [247]. Noncompetitive mGlu antagonists, such as CPCCOEt, MPEP, and BAY36-7620, decrease the maximal effect of glutamate without changing its affinity, clearly indicating that they interact at a site other than the glutamate binding site. Similar to positive allosteric modulators, noncompetitive mGlu receptor antagonists interact with the transmembrane domains [248–250]. Noncompetitive GABA_B antagonists, based on novel chemical structures, have so far not been disclosed.

13.6.3.2 Subtype-Selective Ligands. To date the only prominent molecular distinction in the GABA_B system is based on the two splice variants GABA_{B1a} and GABA_{B1b}. Essentially, these two variants represent the only means for directing the search for novel GABA_B drugs toward molecularly distinct receptor populations. The differential expression patterns of GABA_{B1a} and GABA_{B1b} point to a functional heterogeneity, but it is unknown which physiological effects relate to which isoform. Most importantly, it remains unclear which splice variants are involved in pre- and postsynaptic functions [23, 25, 28, 29, 251–253].

Appreciating the unique roles played by GABA_{B1a} and GABA_{B1b} is essential to fully exploit GABA_B receptors for therapeutic uses. It was argued that the anticonvulsant, antihyperalgesic, and anxiolytic drug gabapentin is able to distinguish the two variants [33, 34]. In particular, gabapentin was claimed to be active at GABA_{B(1a,2)} but not at GABA_{B(1b,2)} receptors. However, in most people's hands gabapentin has no activity at GABA_B receptors [37, 38, 254, 255]. The reason for this discrepancy is unclear. Given the lack of truly selective ligands, it will probably be necessary to take a genetic approach to dissociate in vivo functions of GABA_{B(1a,2)} and GABA_{B(1b,2)} receptors. Mice with selective ablations of the GABA_{B1a} or GABA_{B1b} subunits should allow exposing the influence of splice variants on the manifestation of physiological and behavioral traits. Such mice will also help to evaluate whether compounds specifically targeted to GABA_{B(1a,2)} or GABA_{B(1b,2)} are likely to have distinct enough effects to warrant drug discovery efforts.

13.7 DISEASE

13.7.1 GABA_B Receptors as Therapeutic Targets

GABA_B receptors have been implicated in a wide variety of neurological and psychiatric disorders. To date, two GABA_B drugs are on the market, baclofen (Lioresal) and GHB (Xyrem). Lioresal is used to treat severe spasticity of cerebral and spinal origin. Baclofen is effective in animal models for many central and

peripheral disorders, but side effects and tolerance prohibited a more widespread use of this drug in humans. GHB (Xyrem) has been approved in different countries for general anaesthesia and the treatment of alcohol withdrawal and addiction. In the United States, GHB (Xyrem) is a controlled substance and only approved by the Food and Drug Administration for treating a small population of patients with narcolepsy who experience episodes of cataplexy. It was also marketed as a body-building and fat-burning compound and is widely used and abused as a recreational drug due to the euphoria it produces (for a recent review see [214]). Similarly, GABA_B antagonists show therapeutic promise but their shortcomings (e.g., lack of brain penetration or some proconvulsive potential) hampered clinical development. Nevertheless, the low-affinity compound SGS742 (CGP36742) has recently entered clinical trials in patients with mild cognitive impairment (MCI) [256]. Gene knockout mice support the preclinical and clinical evidence that GABA_B drugs could be used to manage pain, strengthen memory, and treat epilepsy [52, 122, 193]. Moreover, GABA_{B1}^{-/-} and GABA_{B2}^{-/-} mice point at indications that were not necessarily linked to the GABA_B system. For example, these mice exhibit a hyperactive phenotype reminiscent of dopamine transporter DAT knockout mice that are similarly aroused by novelty and respond with hyperlocomotion to a new environment [52, 122, 257]. It is commonly assumed that hyperactive behaviors are related to a hyperdopaminergic state. It is therefore conceivable that the loss of GABA_B control over dopamine release triggers the behavioral abnormalities in GABA_{B1}^{-/-} and GABA_{B2}^{-/-} mice. A GABA_B brake on dopamine release could possibly be exploited to attenuate motor problems of Parkinson's disease or attention-deficit hyperactivity disorder (ADHD) patients. Furthermore, GABA_{B1}^{+/-} mice show enhanced prepulse inhibition when compared to wild-type littermates, suggesting that GABA_{B1} knockout mice exhibit sensorimotor gating abnormalities [193]. Compounds interfering with GABA_B receptors may therefore be beneficial in schizophrenia. Below we discuss some of the most promising indications for GABA_B drugs in more detail.

13.7.2 Addiction

There is now good evidence that GABA_B agonists can reduce the craving for drugs such as cocaine, heroin, alcohol, and nicotine [258]. Preliminary clinical studies with cocaine-abusing patients reported a reduced craving for cocaine following baclofen administration [259, 260]. GABA_B agonists are also effective in clinical studies of alcohol abuse [261]. Studies in animals generally support that baclofen and other compounds acting at GABA_B receptors have a therapeutic effect on abuse of a host of addictive substances (for a recent review see [262]). There is good evidence that this is due to an attenuation of the reinforcing effects of abused drugs in the mesolimbic dopamine system [263, 264]. Drugs of abuse increase extracellular dopamine levels in the accumbens, a brain region that is believed to be involved in the reward and reinforcement circuitry [265, 266]. Activation of GABA_B receptors in the accumbens reduces firing of dopaminergic cells and inhibits the release of dopamine [267]. Altogether, it appears that GABA_B activity blocks the increase in dopamine release that is otherwise induced by drugs of abuse [268]. Accordingly, rats reduce self-administration of cocaine after they receive an injection of baclofen into the accumbens and the ventral tegmental area [269, 270]. Interestingly, different GABA_B

agonist can exert opposing behavioral effects on the reward pathway. Whereas baclofen reduces self-administration and reinstatement of a number of drugs in rodents, GHB is readily self-administered in mice [271] and has a strong abuse potential itself [214]. A recent study by Lüscher and colleagues [129] offered a pharmacological explanation for the difference in abuse liability of GHB and baclofen. A different coupling efficacy of GABA_B receptors to GIRK (Kir3) channels in dopaminergic and GABAergic neurons of the ventral tegmental area may explain bidirectional effects of GABA_B agonists on the mesolimbic dopamine system [129]. Nevertheless, GHB also showed promising effects in situations involving opiate withdrawal and alcohol and nicotine dependence [216] and was shown to decrease cocaine self-administration in rats [272]. Withdrawal from repeated cocaine treatment produces an increase in the basal levels of extracellular GABA in the nucleus accumbens. This results in functional desensitization of GABA_B receptors concomitant with a diminished S892 phosphorylation of the GABA_{B2} subunit [169]. It remains to be addressed whether this functional desensitization of GABA_B receptor after drug withdrawal restricts the therapeutic potential of GABA_B receptor agonists. In conclusion, preclinical and clinical data support that modulation of GABA_B receptors could be used to treat addiction. Positive modulators of GABA_B receptors could be favorable for therapy and avoid some of the side effects of full agonists [273].

13.7.3 Anxiety and Depression

It was proposed many years ago that pharmacological intervention with GABA_B receptors could be effective in the treatment of mood disorders such as anxiety and depression. Chronic exposure to antidepressant drugs was shown to upregulate GABA_B binding sites in the rat frontal cortex [274]. It appears that a decrease in GABA_B-mediated neurotransmission is compensated for by an increase in post-synaptic GABA_B receptor protein. These findings were extended by showing that baclofen inhibits the action of antidepressants [275, 276]. In line with this the antagonist CGP36742 exhibited antidepressive properties in the learned helplessness paradigm in rats [277]. Accordingly, it was proposed that GABA_B antagonists could be effective in the treatment of depression. However, a positive modulation of GABA_B receptors as an antidepressant therapy was also suggested [278].

Similarly, pharmacological intervention with GABA_B receptors was also investigated as a treatment of anxiety disorders. Baclofen showed anxiolytic-like effects in several preclinical tests in rodents [279–282], and reverses the anxiogenic response induced by withdrawal from chronic diazepam and alcohol treatment [283–285]. Moreover, baclofen attenuates the anxiety associated with alcohol withdrawal [286], post-traumatic stress [287], panic disorder [288], and traumatic spinal cord lesions in the clinic [289].

Recently the development of novel pharmacological and genetic tools advanced the knowledge on the role of GABA_B receptors in emotional disorders (for a recent review see [290]). Mice lacking GABA_B receptors show altered depression and anxiety-related behavior in a variety of experimental paradigms [291, 292]. In particular, GABA_{B1}^{-/-} mice display antidepressant-like activity in the forced-swim test, in support of the antidepressant action of GABA_B antagonists. GABA_{B1}^{-/-} as well as GABA_{B2}^{-/-} mice are more anxious than their wild-type counterparts. Moreover, GABA_{B1}^{-/-} mice have a paniclike response in the elevated

zero maze [291]. These data suggest that activation of GABA_B receptors might be anxiolytic. Recent studies with positive modulators of GABA_B receptors (i.e., CGP39783) indeed indicate that such compounds might represent a novel class of anxiolytic with a superior side-effect profile than currently available medication [291, 293]. Taken together, targeting GABA_B receptors with allosteric compounds might provide a useful strategy in the treatment of mood disorders. However, how activation of GABA_B receptors affects depression and anxiety is not understood yet.

13.7.4 Epilepsy

GABA_B receptors have repeatedly been implicated in the etiology of epilepsies. However, the first genetic link between GABA_B receptors and human epilepsy was only provided very recently [294]. It appears that a *GABAB1* polymorphism not only confers a highly increased susceptibility to temporal lobe epilepsy but also influences the severity of the disease.

GABA_B antagonists suppress the absence seizures seen in the *lh/lh* lethargic mice [295] and the genetic absence-epilepsy rats from Strasbourg (GAERS) [296], while agonists exacerbate the seizures. Apparently, blocking of thalamic GABA_B receptors reverses an excess of inhibition that is the cause of absence seizures [100, 297]. It was proposed that GABA_B-mediated IPSPs have a “priming” function toward the generation of low-threshold Ca²⁺ potentials, thereby facilitating burstfiring of the type observed in absence epilepsy [100]. The primary gene defect in *lh/lh* mice is a mutation in the Ca²⁺ channel β subunit, which affects the interaction with the G $\beta\gamma$ subunits of the activated G protein. The phenotype of *lh/lh* mice involves an upregulation of GABA_B binding sites, which is expected to facilitate absence seizure development. Paradoxically, the overt phenotype of GABA_B receptor-deficient mice includes spontaneous seizures, including sporadic absence-type seizures [52, 122, 193, 298]. However, the absence-type seizures seen in the GABA_{B1}^{-/-} mice are not directly comparable to the “typical” absence seizures observed in the GAERS. The seizures in the GAERS are characterized by frequent and short EEG bursts, while the ones seen in the GABA_{B1}^{-/-} mice are rare and of much longer duration. A lack of GABA_B signaling may also underlie the clonic-type seizures in the *weaver* mouse [299]. The *weaver* mouse exhibits a mutation in the *Kir3.2* K⁺-channel gene, which leads to a postsynaptic loss of GABA_B inhibition and to seizure development [121]. Kainic acid-induced seizures in rats are characterized by a downregulation of GABA_B receptor subunits [300, 301]. In contrast, following induction of generalized seizures in rats with electroshock, an upregulation of the GABA_{B1b} mRNA, but not of the GABA_{B1a} mRNA, was observed [302]. This suggests a selective involvement of GABA_B isoforms in the regulation of electroshock-induced seizure activity.

To date, the data indicate that GABA_B compounds could be most useful in the pharmacotherapy of absence seizures in children. The finding, however, that high doses of certain GABA_B antagonists induce convulsions in rats renders clinical trials problematical [303]. Clearly, a wide therapeutic window will be a critical requirement when entering clinical trials with GABA_B antagonists.

13.7.5 Nociception

Baclofen exerted antinociceptive effects in clinical trials involving trigeminal, glossopharyngeal, vagoglossopharyngeal and ophthalmic-postherpetic neuralgias,

diabetic neuropathy, and migraine [101, 304–306]. Although baclofen is used clinically to treat neuropathic pain and, when administered intrathecally, to attenuate pain associated with spinal injury [307] or stroke [308], its use as a general analgesic is limited because of its sedative properties and the rapid development of tolerance to its pain-relieving activity. Baclofen also exhibited antinociceptive properties in rodent models of acute pain, such as the tail-flick, acetic acid writhing, formalin, and hot-plate tests [309, 310]. Moreover, baclofen showed antinociceptive and antiallodynic actions in chronic pain models in rats [311, 312]. Baclofen likely exerts its effects in both the spinal cord [313] and brain [314, 315]. It has been suggested that an inhibitory tone exerted via GABA_B receptors can control primary afferent-mediated activation of dorsal horn projection neurons in rats and monkeys [316, 317]. Recently, a study by Nagy and colleagues provided an alternative mechanism [318]. They showed that GABA_B receptors exert a direct control on dorsal horn neuron excitability in rat spinal cord slice preparation. One of the few cortical areas consistently activated by painful stimuli is the rostral agranular insular cortex (RAIC) where GABA robustly inhibits neuronal activity [314]. Selective activation of GABA_B receptor-bearing RAIC neurons produces hyperalgesia through projections to the amygdala, an area involved in the control of pain and fear. In the dorsal horn of the spinal cord, baclofen inhibits the release of glutamate and substance P from both large and small fibers [39]. This explains why intrathecal application of baclofen relieves central pain in patients with spinal lesions [307] or after cerebral strokes [308]. Acute pain tests with GABA_B receptor-deficient mice support that GABA_B receptors participate in nociceptive pathways [52, 122]. GABA_{B1}^{-/-} as well as GABA_{B2}^{-/-} mice exhibit pronounced hyperalgesia to noxious heat in the hot-plate and tail-flick tests as well as reduced paw withdrawal thresholds to mechanical pressure. Changes in the noxious thermal and mechanical threshold suggest that there is a loss of intrinsic GABA_B tone in the nociceptive system of GABA_B-deficient mice. The lack of GABA_B receptors most probably results in an increased central hyperexcitability of the spinal nociceptive pathways.

13.7.6 Tumor Cell Growth and Migration

An emerging topic is the involvement of GABA_B receptor signaling in the control of tumor cell growth and migration. It is suggested that GABA_B receptors control the migration and vectorial growth of cells in the nervous system [319–322]. Masaharu Tatsuta and colleagues were the first to show that systemic administration of baclofen significantly reduces the incidence and number of gastric cancers in rats and attenuates azoxymethane-induced carcinogenesis in rat colon [323, 324]. Similarly, baclofen completely inhibited the noradrenaline-induced migration of SW480 colon carcinoma cells [325], supporting that baclofen or the newly available allosteric modulators could be used to prevent cancer cell migration.

13.7.7 Genetic Linkage Studies

The *GABA_{B1}* and *GABA_{B2}* genes map to human chromosomes 6p21.3 and 9q22, respectively [326, 327]. Given the potential implication of GABA_B receptors in the etiology of epilepsies (Section 13.7.4) a number of studies addressed a direct involvement of the *GABA_{B1}* gene. The result of a recent study indicates that a

GABA_{BI} polymorphism, G1465A, indeed confers a highly increased susceptibility to temporal lobe epilepsy [294]. This polymorphism also influences the severity of this common epileptic disease. This agrees with earlier studies that proposed a dysfunctional *GABA_B* system as one of the causes of temporal lobe epilepsy [301, 328, 329]. A possible involvement of *GABA_{BI}* receptors in idiopathic generalized epilepsies was investigated in linkage and association studies [330, 331]. Yet another study explored a link to childhood absence epilepsy [332]. However, these latter studies provided no evidence for an involvement of *GABA_{BI}* polymorphisms in these two other forms of epilepsy. Similarly, Anaya and colleagues found no linkage between the *GABA_{BI}* gene and epilepsy in Caucasian patients [333]. Other linkage studies addressed a possible involvement of the *GABA_{BI}* gene in conditions of alcohol dependence [331] and in panic disorders [334]. However, *GABA_{BI}* polymorphisms do not account for the genetic variance of alcohol dependence, nor is there an indication for increased vulnerability to panic disorders. The *GABA_{B2}* gene also maps to a number of disease loci. Most importantly, *GABA_{B2}* is located within a region of chromosome 9q12 that showed a linkage to nicotine dependence [335]. A recent study provided evidence of a significant association of *GABA_{B2}* variants with nicotine dependence, implying that this gene plays a role in nicotine addiction [336]. *GABA_{B2}* also maps in the vicinity to the locus for hereditary sensory neuropathy type 1 (HSN-1) [327]. However, a possible involvement of *GABA_{B2}* in the etiology of HSN-1 has not yet been investigated.

14.1 INTRODUCTION

Cells create differences in voltage and ion concentration across membranes through the action of adenosine 5'-triphosphate (ATP)-dependent ion pumps, and the dissipation of these electrochemical gradients through ion channels underlies the generation and propagation of action potentials, release of hormones and neurotransmitters, and many other functions essential for cellular signaling and homeostasis. Mammalian cell membranes typically maintain a resting membrane potential of -50 to -90 mV, a range that is close to the equilibrium potential for potassium (K^+) and far from the equilibrium potentials for sodium (Na^+) and calcium (Ca^{2+}). Relatively voltage-insensitive background K^+ channels maintain hyperpolarized membrane potentials at rest, resisting the depolarizing shifts in membrane potential that open voltage-dependent Na^+ , K^+ , and Ca^{2+} channels.

A sufficiently strong depolarizing stimulus, such as a sodium current through an ionotropic glutamate receptor, can precipitate an action potential by initiating the sequential opening and closing of voltage-gated ion channels. Voltage-gated Na^+ channels open earliest and further depolarize the membrane before they inactivate and become nonconductive. More slowly activating voltage-gated K^+ channels then open and return the membrane toward its resting potential before they inactivate. Voltage-gated Ca^{2+} channels also open upon depolarization, stimulating neurotransmitter release as well as longer term (e.g., transcriptional) effects that depend on calcium as a second messenger.

It is clear from the roles of voltage-gated ion channels in the neuronal action potential that channels must be selective for a specific ion and must open and inactivate within the proper voltage range. The conformational changes that lead to opening and closing of channels are known as “gating” and occur in response to stimuli such as ligands or voltage. Selectivity and gating depend on structural elements of the channel proteins, and X-ray crystallographic studies in the last few years have provided the first high-resolution insights into the three-dimensional organization and functional properties of channels. However, before the channels can affect cellular physiology, they must fold properly, coassemble with homologous or auxiliary subunits, and reach the plasma membrane through the secretory pathway. While gating and selectivity have been tractable properties to study with electrophysiological techniques for decades, only recently have genetic, molecular biological, biochemical, and immunological approaches enabled channel biologists

to understand the pre- and posttranslational modification, assembly, and trafficking of ion channels.

With so many levels of regulation of ion channel activity, one can imagine that mutations of ion channels at critical amino acid residues could lead to various defects in channel folding, trafficking, or conduction. Indeed, a number of ion channel-related diseases, or channelopathies, have been described, including epilepsy, arrhythmia, myotonia, diabetes, and even cancer, in humans. In addition, animal models, particularly mouse and the fruit fly *Drosophila melanogaster*, have helped to reveal the physiological roles of both wild-type and mutant channels.

As the roles that channels play in pathophysiology become clearer, the importance of developing pharmacological tools to manipulate channel function grows. Nature has provided many highly specific channel blockers in the form of peptide toxins from venomous snakes, spiders, sea snails, scorpions, and other species. While useful for laboratory studies, these toxins have poor bioavailability, so the identification and development of organic small-molecule blockers and openers have become important goals of pharmacological research.

This review will give an overview of the current state of knowledge about the structures of ion channels; the mechanisms of selectivity and gating; the cell biology of ion channels, including coassembly of channel subunits with other proteins and trafficking of ion channels; the physiological functions of ion channels and their roles in disease; and pharmacological tools available for the manipulation of ion channels in vitro and in vivo. While a vast array of ion channels exist with different selectivities and mechanisms of activation, this chapter will focus on voltage-gated K^+ , Na^+ , and Ca^{2+} channels.

14.1.1 Cloning and Evolutionary Relationships

Cloning of the first voltage-gated ion channel, from the eel *Electrophorus electricus*, showed four repeats of a six-transmembrane segment (TMS) topology, with a highly charged fourth TMS in each repeat [1]. Further cloning of other voltage-gated channels indicated that an amphipathic α helix, with an arginine residue approximately every fourth residue, is a conserved motif among voltage-gated ion channels. This charged helix appeared to be a region of the channel that might be sensitive to changes in transmembrane potential.

Identification of the genes for voltage-gated K^+ channels, beginning with the *Shaker* mutant of *Drosophila* [2, 3], revealed an evolutionary relationship among voltage-gated ion channels. Whereas the Na^+ and Ca^{2+} channels contain four pseudorepeating domains (D_{I-IV}), each containing six TMSs, the voltage-gated K^+ channels are made up of only one domain of six TMSs and assemble as tetramers (Fig. 14.1). Thus, it appears that voltage-gated sodium and Ca^{2+} channels emerged evolutionarily by successive gene duplications from a K^+ channel precursor. With the sequencing of genomes of organisms from all kingdoms of life, it is clear that voltage-gated ion channel genes are both ancient and ubiquitous. The Na^+ channels of 24-TMS topology have been found in some lower organisms, such as cnidarians and ctenophores [4], and one 24-TMS voltage-gated Ca^{2+} channel is present in the yeast *Saccharomyces cerevisiae* [5]. Among the voltage-gated cation channels, only K^+ channels are present in prokaryotes, though a Na^+ channel of 6-TM topology

Figure 14.1 Voltage-gated ion channels. *Cylinder*: transmembrane segment. Lines indicate polypeptide chains but are not proportional to a particular polypeptide length of a channel or subunit. *Circles and ellipses*: auxiliary subunits. Pitchforks: sites of probable N-linked glycosylation. (a) Voltage-gated sodium channel and two β subunits. The DEKA selectivity filter and soleucine–phenylalanine–methionine (IFM) inactivation motif are shown. (b) Voltage-gated calcium channel along with γ , β , and $\alpha_2\delta$ subunits. The EEEE selectivity ring is shown. (c) Voltage-gated potassium channel. The GYG selectivity filter and N-terminal inactivation ball are displayed.

from *Bacillus halodurans* has been cloned and characterized [6]. Bacterial K^+ channels that can be overexpressed and purified in large quantities provided the raw materials for the X-ray crystallographic studies that show the details of ion selectivity and voltage sensing at an atomic level.

14.1.2 Nomenclature

The naming of ion channels has been an idiosyncratic process over the years, as researchers named channels for mutant or knockout phenotypes, or with acronyms derived from channel functional properties. For example, K^+ channels related to the *Shaker* channel from *Drosophila* have alternately been called Shaker, $K_v1.x$, or KCNA channels. In the interest of consistency, we will follow the International Union of Basic and Clinical Pharmacology (IUPHAR) nomenclature for voltage-gated sodium (Na_v) (Fig. 14.2a) [7] and Ca^{2+} channels (Ca_v) (Fig. 14.2b) [8]. For voltage-gated K^+ channels (Fig. 14.3a), we use K_v names for the A-type and delayed rectifier channels $K_v1.x$, $K_v2.x$, $K_v3.x$, $K_v4.x$, $K_v5.1$, $K_v6.x$, $K_v8.1$, and $K_v9.x$. We use the more common literature names for the KCNQ1–5 channels and for the calcium-activated K^+ channels of large (BK), intermediate (IK), and small (SK) conductance. The more widely used *Drosophila*-derived names EAG (ether-à-go-go), ERG (ether-à-go-go-related gene), and ELK (ether-à-go-go-like gene) are employed instead of KCNH1–8 or $K_v10.x/K_v11.x/K_v12.x$ [9].

14.2 POTASSIUM CHANNELS

K^+ channels are essential in both excitable and nonexcitable cells for the control of membrane potential, regulation of cell volume, and secretion of salt, neurotransmitters, and hormones. They allow the selective, diffusional passage of potassium ions across biological membranes and are capable of up to 10,000-fold selectivity of potassium over sodium. Voltage-gated K^+ channels, unlike the related voltage-gated Na^+ and Ca^{2+} channels, are expressed not only in heart, neurons, and muscle cells but also in many nonexcitable cells.

While best known for their role in repolarizing the membrane of neurons and cardiomyocytes during an action potential, K^+ channels are, in fact, expressed in most mammalian cell types. They play a critical role in such diverse processes as epithelial salt balance across epithelial cells, particularly in the kidney and colon, T-cell signaling, and insulin release by pancreatic β cells. Accordingly, a growing number of K^+ channels are potential targets for treatment of diseases. For example, missense mutations in KCNQ2 or KCNQ3 that reduce M-channel current cause an autosomal dominant form of seizure disorder, benign neonatal familial convulsions. And a number of voltage-gated K^+ channel mutations can cause arrhythmias by delaying the repolarization phase of the cardiac action potential.

With the sequencing of the human genome, over 80 K^+ channel genes have now been identified and can be grouped into several classes based on their transmembrane (TM) topologies. The inwardly rectifying K^+ channels have two TMSs flanking the highly conserved pore region, or P loop, which confers potassium selectivity (see Section 14.2.2), and assemble as tetramers. The two-P, or KCNK channels, consist of two inward rectifier-type domains linked together and function as dimers. The voltage-gated and calcium-activated K^+ channels have an inward rectifier-type topology, containing the conserved P loop, preceded by four TM domains (five in the case of BK channels) (Fig. 14.1c). A highly charged fourth TMS functions as the voltage sensor in the voltage-gated channels. The N- and C-terminal domains of K^+

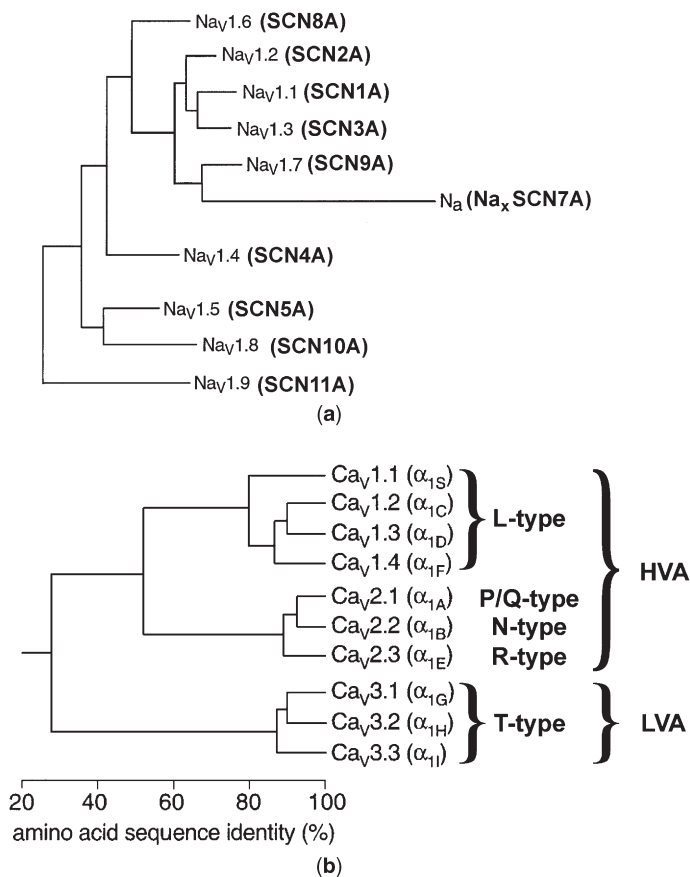

Figure 14.2 (a) Phylogenetic relationships by maximum-parsimony analysis of rat sodium channel sequences Nav1.1 through Nav1.9 and Na_x. To perform the analysis, the amino acid sequences for all of the isoforms were aligned using CLUSTAL W. The amino acid sequences in the alignments were then replaced with the published nucleotide sequences, and the nucleotide sequence alignments were subjected to analysis using the program PAUP*. Divergent portions of the terminal regions and the cytoplasmic loops between domains I–II and II–III were excluded from the PAUP* analysis. The tree was rooted by including the invertebrate sodium channel sequences during the generation of the tree, although these sequences are not shown. (Modified from [7]). (b) Sequence similarity of voltage-gated calcium channel α_1 subunits. Phylogenetic representation of the primary sequences of the calcium channels. Only the membrane-spanning segments and the pore loops (~350 amino acids) are compared. First, all sequence pairs were compared, which clearly defines three families with intrafamily sequence identities above 80% (Ca_v1, Ca_v2, Ca_v3). Then, a consensus sequence was defined for each family and these three sequences were compared with one another, with interfamily sequence identities of ~52% (Ca_v1 v. Ca_v2) and 28% (Ca_v3 v. Ca_v1 or Ca_v2). (Modified from [8].)

channels are cytoplasmic and can regulate channel electrophysiological properties and trafficking and can be a platform for phosphorylation, channel–lipid interactions, and coassembly with other proteins. In addition to these pore-forming, or α , subunits, a number of cytosolic and TM proteins coassemble with K⁺ channels and

alter channel sensitivity to various ligands or to voltage or regulate subcellular localization of the channel complex.

The last six years have brought high-resolution structures of several bacterial K^+ channels as well as cytoplasmic domains and β subunits of several mammalian channels. The structure of KcsA in 1998 [10] showed the atomic details of potassium coordination by the selectivity filter (Fig. 14.3b). While the KcsA structure shows a channel in the closed state, the structure of the calcium-activated MthK [11] revealed the conformation of an open channel. A structure of the voltage-gated K^+ channel, K_v AP, was published in 2003 [12], but there is still much debate regarding the organization of TM helices of this class of channels and the conformational changes involved in voltage gating [13]. The increasing use of structural biology as a tool for studying ion channels will allow for more detailed understanding of gating, selectivity, disease-causing mutations, and the interactions between channels and the drugs that modulate them.

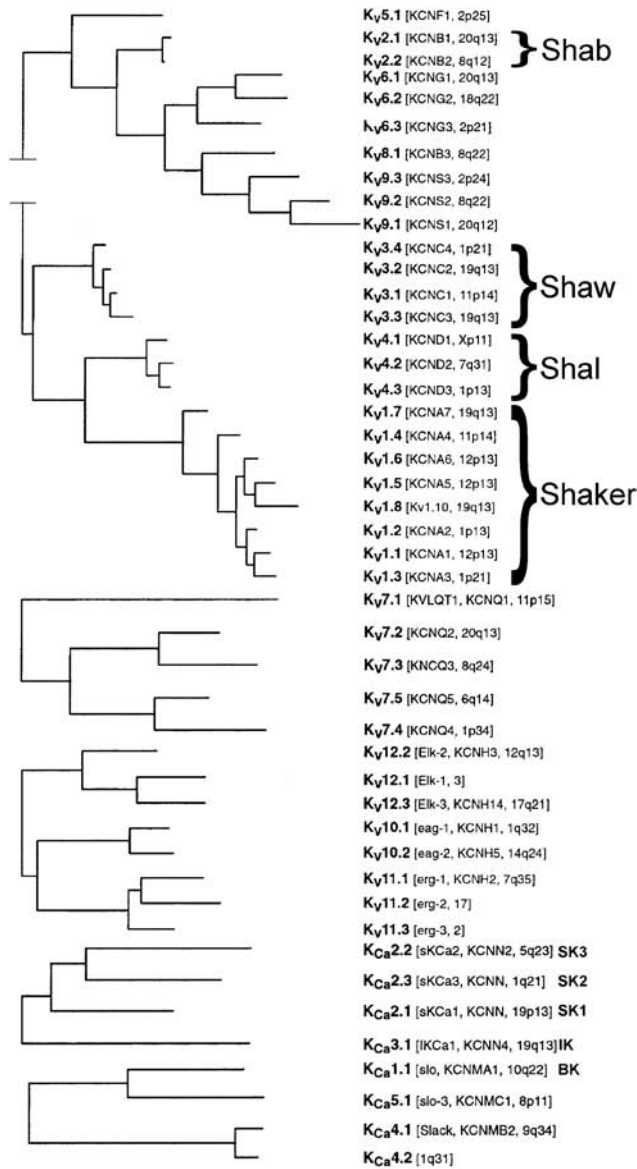

A vast pharmacology exists for K^+ channels, including many peptide toxins isolated from microbes and venomous animals and therapeutically more useful small organic compounds. Many of these agents act on multiple K^+ channels subtypes, on account of the conserved structural elements among K^+ channels, while others show potent specificity for a single channel subtype.

14.2.1 Voltage-Gated K^+ Channels

Voltage-gated K^+ channels are generally divided into subgroups depending on sequence homology and the ability to heteromultimerize. The three Shal K^+ channels (K_v 4.1–4.3, or KCND1–3), for example, can coassemble with each other but not with Shaker (K_v 1.1–1.8, or KCNA1–8) K^+ channels. The K_v channels activate upon depolarization and inactivate through either fast or slow inactivation and are also known as delayed rectifiers, since upon depolarization they repolarize the membrane after a delay. Other voltage-gated K^+ channels, the KCNQ channels and KCNH [human ether-à-go-go-related gene (HERG), EAG, ELK] channels, activate more slowly and are known as slow delayed rectifiers. While electrophysiological studies have demonstrated the diverse activation and inactivation properties of voltage-gated K^+ channels, high-resolution structural studies and spectroscopy are beginning to provide detailed molecular models for the voltage-dependent properties of these channels.

14.2.2 Selectivity

The region of K^+ channels responsible for selectivity, the P loop, was identified more than a decade ago by sequence alignment and mutagenesis studies, and a tripeptide motif Gly–Tyr–Gly was found to be crucial for distinguishing potassium from other monovalent cations [14]. It was not until MacKinnon and colleagues solved the crystal structure of the KcsA channel from *Streptomyces lividans* [10] that the geometry of potassium coordination by the channel pore became clear (Fig. 14.3b). The four subunits of the K^+ channel symmetrically surround the permeating potassium ions of the structure, with the channel reaching its narrowest point at the GYG region of the P loop. In this region, known as the selectivity filter, rings of four carbonyl oxygens coordinate potassium ions as they move through the

(a)

constriction in single file. The oxygens, in effect, mimic the hydration sphere of a potassium ion in solution and therefore lower the dehydration energy required to move the ion from bulk solvent into the protein channel. The geometry of the pore provides a more favorable coordination sphere for potassium than for sodium, which has a smaller atomic radius and a higher dehydration energy. Some have argued recently, though, that the channel pore may not be rigid and that the nature of carbonyl dipole moments themselves favor potassium over sodium [15].

Conduction occurs in the direction of the electrochemical gradient for potassium at rates approaching the diffusion limit. Repulsion between closely spaced potassium ions in the selectivity filter facilitates such rapid conduction [10]. The narrow-selectivity filter makes up less than a third of the distance of the conduction pathway, and the rest of the channel pore is wide enough to contain water molecules that hydrate ions as they pass through the inner cavity. Thus, each ion is only briefly dehydrated. Ions in the water-filled cavity below the selectivity filter are further stabilized by the orientation of negative dipoles of the four pore helices toward the cavity.

14.2.3 Voltage Activation

With the cloning and sequencing of the first voltage-gated K^+ channels, *Shaker* from *D. melanogaster* in 1987 [3], and the previously cloned voltage-gated sodium and Ca^{2+} channels, it became clear that the charged S4 TMS was likely to be important for voltage sensing. Electrophysiological studies had already shown that a “gating current” of 12–13 charges precedes the conduction of ions through the channel, indicating that a charged part of the channel protein moves across the TM electric field in a voltage-dependent manner [16]. Site-directed mutagenesis of basic residues in S4 confirmed the importance of S4 in voltage gating [17]. Later experiments showed that acidic residues in the S2 and S3 segments are important for stabilizing S4 basic residues within the membrane [18]. Based on the presumed topology of the channel and the magnitude of gating currents, several models for voltage sensor movement were proposed [4]. The S4 helix might undergo a simple translation, altering the register of S2–S4 and S3–S4 interactions and exposing some S4 residues to the extracellular solution. Alternatively, voltage sensing could be a combination of helical translation and rotation of S4. Resonance energy transfer experiments measured relatively small changes in the distance of S4 segments relative to one another, results not consistent with dramatic conformational changes [19, 20]. A way to reconcile the measured distances with the necessity of moving 12–13 charges through the TM electric field is a thinning of the membrane around S4 such that four basic residues could move from the cytoplasmic side of the membrane to the extracellular side with only a modest translation and rotation.

Figure 14.3 (a) Phylogenetic trees of the K_V and K_{Ca} channel families. An amino acid sequence alignment made using CLUSTAL W was subjected to analysis by maximum parsimony (PAUP*). Only the hydrophobic core region of the alignment was used for analysis. (Modified from [9].) (b) KcsA structure. Two subunits of KcsA are shown. The GYG motif required for K^+ selectivity is highlighted. Figure originally prepared with MOLSCRIPT and RASTER-3D. (Modified from [10].)

The structure of the bacterial voltage-gated K^+ channels K_vAP showed an unexpected orientation of S1–S4, with an S3–S4 voltage-sensing “paddle” on the outer edge of each subunit and touching lipid [12]. The data led MacKinnon and colleagues to propose that the voltage paddle is flexible and can swing across the bilayer upon voltage activation [21]. A caveat of the crystallization procedure, however, was the use of an antibody against the S3–S4 region to cocrystallize with the channel. The antibody likely distorted the voltage-sensing portion of the channel so that it may not be resting in its normal position for the depolarized state (assuming that crystallization in detergent mimics the 0 mV state of the channel). In addition, parts of the structure that appear to be on the cytoplasmic side of the membrane in the structure are glycosylated in homologous mammalian channels, suggesting that they are unlikely to move through the membrane [13]. Thus, the mechanics of voltage sensing are still an open question that will require more high-resolution structural and computational studies before it can be answered definitively.

14.2.4 Gating

Diverse stimuli can cause channel opening and closing, a process known as “gating,” and their effects must ultimately affect potassium movement through the permeation pathway of the channel. Structural and spectroscopic studies coupled with measurements of the solvent accessibility of residues in open versus closed states have identified two “gates” that restrict ion permeation. One is at the cytoplasmic face of the channel, where the inner pore-lining helices constrict and can block ion passage through the narrow opening. This region was mapped through the differential accessibility of cysteine-modifying reagents to cysteine mutations in S6 in the open and closed states [22]. Structures of the KcsA channel, which is presumably in the closed state [10], and MthK, a calcium-sensitive channel in the open state [11], confirmed this result. The KcsA structure has straight pore-lining helices that constrict at the cytoplasmic side to limit access to the selectivity filter. MthK, when opened by calcium, swings open its pore helices around a glycine hinge in M2 (S6) such that there is an opening of 12 Å from the cytoplasm to the inner pore. While voltage-gated K^+ channels may make use of this glycine hinge, they also have a Pro–X–Pro motif (though K_vAP lacks this element) at the cytoplasmic mouth of the channel that acts as a hinge and may make the opening narrower than that of MthK [23]. Interestingly, this more constricted opening may explain in part the 10-fold lower conductance of K_v channels compared to MthK.

The second gate is at the selectivity filter, which can adopt a conformation that prevents permeation of ions. This kind of gating underlies C-type (slow) inactivation of K_v channels, an inactivation mechanism that persists in the absence of fast inactivation (see below) and is dependent on the extracellular potassium concentration. The structure of KcsA in the presence of low potassium (3 mM) shows a collapsed structure that coordinates fewer potassium ions than the high-potassium (200 mM) structure [24]. The structure of a bacterial inwardly rectifying K^+ channels has a slightly different pore structure and also appears to be a nonconducting form [25] that may represent a C-type inactivated conformation.

A related question for voltage-gated channels is how voltage sensing is coupled to the channel gates to allow for opening following the movement of a gating current. During voltage sensing, the S4 domain's charged residues move outward, likely

exerting tension on the S4–S5 linker. Some studies have suggested that this linker interacts with the C-terminal end of S6 in the HERG K^+ channels [26].

14.2.5 Fast Inactivation

A-type, or rapidly inactivating, K^+ channels inactivate on a scale of tens to hundreds of milliseconds after depolarization. This inhibition is mediated by a peptide of about 30 amino acids either at the N-terminus of the channel or at the N-terminus of a β subunit (Fig. 14.4a). The peptide binds to the cytoplasmic side of the K^+ channel pore and prevents ion conduction until it is reversed by repolarization [27]. Although no structure of the inactivation peptide bound to the pore has been solved, the prevailing model has been the “ball and chain.” The N-terminal ball of basic and hydrophobic residues is tethered by a chain of linker residues to the T_1 domain or β subunit and probably snakes through the space between the T_1 domain and the membrane in order to reach the pore [28]. The ball residues are not well conserved among channels, but hydrophobic residues seem to be of particular importance in binding to the pore [29].

14.2.6 Interacting Proteins

There are many cytoplasmic proteins that have been found to interact with voltage-gated K^+ channels and to alter the electrophysiological properties or localization of the pore-forming α subunits. The β subunits exist in three forms, β_{1-3} , β_1 and β_3 having several splice variants, and coassemble with $K_v \alpha$ subunits in the endoplasmic reticulum (ER) [30]. While β_1 and β_3 are capable of converting slowly inactivating delayed rectifiers to transient A-type currents (Fig. 14.4a) [31], β_2 seems primarily to increase K_v surface expression. These subunits are members of the aldo-keto

Figure 14.4 (a) Voltage-dependent activation and inactivation properties of A-type potassium currents elicited in *Xenopus* oocytes upon expression of $K_v1.1$ (α) or coexpression of α and $K_v \beta_1$ (β) subunits. Outward currents were recorded in the two-electrode voltage-clamp configuration. Current traces recorded after depolarizing pulses to +60 mV from a holding potential of −100 mV. (From [31].) (b) Noninactivating sodium currents. Sodium current was elicited by a 200-ms depolarization from −120 to 10 mV. TTX-sensitive currents were obtained by digital subtraction of sodium currents recorded before and after TTX addition. Peak sodium currents were normalized. Inset shows an expanded y axis scaled to emphasize the relative proportion of noninactivating current. (From [190].)

reductase family and bind NADPH. The function of the cofactor is not clear, and while mutation of catalytic residues seems to have no effect on trafficking of β_2 subunits, disruption of the cofactor binding site leads to improper targeting of α subunits [32]. Large-conductance calcium-activated K^+ (BK) channels interact with another type of β subunit, which has two TMSs and modifies the voltage activation and calcium sensitivity of the BK α subunits.

A second class of proteins that directly affect voltage-gated potassium activity is the KChIPs (K^+ channel interacting proteins), which interact primarily with members of the K_v4 (*Shal*) subfamily. KChIPs are cytoplasmic calcium binding proteins that have four EF-hand Ca^{2+} binding motifs and bind to the N-terminal domain of $K_v4.x$ channels. KChIPs1–3 affect α -subunit activity similarly, by increasing current density, shifting the voltage activation curve to more hyperpolarized potentials, speeding up recovery from inactivation, and slowing the time constant of inactivation [33]. KChIP4 may compete competitively with other KChIPs, fails to increase current density, and can remove rapid inactivation from $K_v4.x$ currents [34].

KCNE (MinK and MiRP) proteins are a class of TM subunits that modulate voltage-gated K^+ channel function. They contain a single TM helix with a glycosylated, extracellular N-terminus and a cytoplasmic C-terminal domain. KCNE1 assembles with KCNQ1 to form the slow component of the cardiac delayed rectifier K^+ current (I_{K_s}), part of the repolarization phase of the cardiac action potential. Its effect on KCNQ1 is to slow voltage activation and increase conductance, and mutations in KCNE1 that reduce KCNQ1/KCNE1 conductance can be arrhythmogenic [35]. KCNE1 can also interact with $K_v4.3$ and decreases its activation and inactivation rates while increasing current density [36], while KCNE3 has been found to co-immunoprecipitate with and affect the electrophysiological properties of $K_v2.1$ and $K_v3.1$ [37].

Cytoskeletal and scaffolding proteins may help to target or maintain voltage-gated K^+ channels at specific subcellular locations. Filamin, an actin binding protein, colocalizes with $K_v4.2$ and may aid in the synaptic targeting of this channel [38]. Integrins, a type of cell adhesion molecule, may help to maintain $K_v4.x$ channel complexes at the neuromuscular junction [39] and interact with $K_v1.3$ in T lymphocytes. The scaffolding protein PSD-95 can mediate synaptic clustering of K_v channels with other channels and signaling proteins [40].

14.2.7 Physiological Functions, Disease Relevance, and Pharmacology

14.2.7.1 K_v Channels. The thresholds of voltage activation and localization play key roles in the physiological function of the various K_v subunits. K^+ channels that activate at subthreshold potentials will tend to resist excitation near the resting potential, while channels that activate at more depolarized potentials will tend to play a more important role in the repolarization phase of an action potential. Axonal or axon terminal K^+ channels shape action potentials and modulate neurotransmitter release, whereas somatodendritic channels affect synaptic integration and shape backpropagating action potentials.

K_v1 channels are predominantly localized to axonal nodes of Ranvier (the juxtaparanodal region) and nerve terminals [41], though they have also been found in somatodendritic membranes [42]. Their main functions at axonal locations are

repolarization during an action potential and spike broadening at the terminal in order to regulate calcium influx and thereby neurotransmitter release. K_v1 channels form sustained currents, except when they contain a $K_v1.4$ subunit or β_1 subunits that confer fast inactivation. $K_v1.5$ is expressed in the heart, where it makes up the ultra-rapidly activating K^+ current [43], a part of the repolarization phase of the cardiac action potential, while $K_v1.3$ modulates T-lymphocyte activation by promoting calcium influx at hyperpolarized potentials [44].

K_v2 channels produce sustained currents that are localized predominantly in the cell body and dendritic membranes. $K_v2.1$ has a more restricted distribution in the soma and proximal dendrites [45], while $K_v2.2$ is found along the length of dendrites [46]. The α subunits $K_v5.1$, 6.1–6.3, 8.1, and 9.1–9.3 are all nonfunctional when expressed alone in heterologous systems. However, many of them can coassemble with K_v2 channels, acting as dominant negatives in some cases and increasing conductance in others [47, 48].

The four K_v3 channels can make up either transient or sustained currents and have more depolarized thresholds for voltage activation (>-10 mV) than most other K_v channels. Coupled with their rapid deactivation (within milliseconds), this high threshold makes these channels suited to their role in high-frequency spiking neurons [49]. Accordingly, K_v3 expression has been observed in most types of high-frequency firing neurons, such as neocortical interneurons [50] and auditory principal neurons [51].

The three K_v4 channels all form A-type currents that are expressed predominantly in somatodendritic membrane. This localization implies that K_v4 channels play a role in synaptic integration and backpropagating action potentials, which are of particular importance for informing dendritic membranes of neuronal firing activity. Their coincidence with subthreshold postsynaptic inputs can lead to synaptic plasticity through long-term potentiation. Immunohistochemistry [52] and electrophysiological studies [53] suggest that K_v4 channels, especially $K_v4.2$, are likely to mediate the A-type currents in dendrites of hippocampal pyramidal neurons. These currents increase in density with distance from the soma, leading to a dampening of backpropagating action potential amplitude in distal dendrites [54]. The inhibition of A-type potassium currents by neurotransmitter receptor-coupled phosphorylation [55] provides a mechanism for increasing backpropagating action potential frequency and *N*-methyl-D-aspartate (NMDA) receptor activation. K_v4 channels are also responsible for the transient outward potassium current ($I_{K,to}$) during the repolarization of the cardiac action potential, as $K_v4.2$ knockout mice lack this $I_{K,to}$ [56]. This current likely consists of $K_v4.2/3$ subunits and KChIP2, since a gradient in KChIP2 expression across the ventricular wall reflects the increase in $I_{K,to}$ in the epicardium compared to the endocardium [57].

Despite their ubiquitous expression in both excitable and nonexcitable cells, K_v channel mutations have been implicated in a relatively small number of diseases. Mutations in $K_v1.1$ can cause episodic ataxia type 1 (EA-1), an autosomal dominant disorder characterized by stress- or alcohol-induced attacks of imbalance and loss of coordination. EA-1 and its associated loss-of-function mutations cause an increase in action potential duration, repetitive firing, and elevated neurotransmitter release. These EA-1 mutations yield either nonfunctional channels or channels with impaired $K_v \beta_1$ -mediated N-type inactivation [58]. An intriguing pharmacological mystery with episodic ataxia is the ability of the carbonic anhydrase inhibitor acetazolamide to relieve attacks [59]. In addition to this $K_v1.1$ disorder, $K_v4.3$, in accordance with

its importance in the cardiac transient outwardly rectifying K^+ channels, has been found to be downregulated in paroxysmal atrial fibrillation [60].

The most potent blockers of K_v channels are toxins from a variety of venomous creatures, which can block either a single channel type or a range of voltage-gated channels with high affinity. Since peptide toxins make poor pharmaceutical agents, however, the channel blockers used clinically are smaller, less specific organic compounds. The least specific blockers, Ba^{2+} , Cs^+ , and tetraethylammonium (TEA), are simply cationic species that block the conduction pathway, whether they are applied to the inner or outer face of the channel. Another general blocker of K^+ channels is 4-aminopyridine, which blocks voltage-gated channels at micromolar to millimolar concentrations and likely acts at the cytoplasmic opening of the channel [61]. A slightly more potent inhibitor is quinidine, an antiarrhythmic derivative of the antimalarial drug quinine and a voltage-dependent open channel blocker [62].

Dendrotoxins are potent peptide toxins from the venom of mamba snakes that have nanomolar affinities for K_v channels. Dendrotoxin K is specific for $K_v1.1$, while α -dendrotoxin targets A-type potassium currents and β - and γ -dendrotoxins block primarily noninactivating potassium currents. The scorpion peptide margatoxin and stichodactyla toxin from sea anemone inhibit $K_v1.3$ at nanomolar concentrations and can block experimental autoimmune encephalomyelitis [63]. The prospect of $K_v1.3$ blockers as immunosuppressants has made the development of small-molecule inhibitors a promising endeavor [64, 65]. Other selective peptide toxins include BDS-I and BDS-II, from sea anemone, which block $K_v3.4$, and the spider toxin heteropodatoxin-2 and phrixotoxin-2 from tarantula, which are selective for K_v4 channels.

14.2.7.2 Large-Conductance Calcium-Activated K^+ Channels. Large-conductance calcium-activated K^+ (BK) channels are voltage dependent, have an intrinsic calcium-sensing ability and a conductance ranging from 100 to 250 pS, and play diverse roles in neuronal and nonneuronal tissues. In hippocampal neurons, they mediate both the repolarizing phase of an action potential and the fast after-hyperpolarization and respond directly to calcium influx through N-type Ca^{2+} channels [66]. And in adrenal chromaffin cells, the hypothalamic–pituitary–adrenocortical stress axis modulates epinephrine release by alternative splicing of messenger ribonucleic acid (mRNA) of BK channels, which regulate hormone release [67]. In the cochlea, a gradient of BK splice variants– β subunit complexes with varying kinetics underlies frequency tuning along the cochlear hair cell membrane [68]. The gradient makes those hair cells with more slowly gating BK channels (more β subunit) tuned to lower frequencies, while hair cells sensitive to higher frequencies have faster gating BK channels (less β subunit). Deletion of BK causes hearing loss in knockout mice and seems to be correlated with down regulated KCNQ4 expression in outer hair cell membrane that leads to degeneration of those cells [69]. BK is the most abundant channel in vascular smooth muscle, and channel composition is important in regulating vascular tone, since impaired β -subunit expression leads to increased vasoconstriction and hypertension [70]. More recently, BK channels have been found to be essential for killing of certain microorganisms by neutrophils and may function by promoting the release of microbicidal serine proteases into the phagosome [71].

There are several peptide toxins that block BK channels specifically, including iberiotoxin, slotoxin, and BmBKTx1, all of which are from scorpion venom. Charybdotoxin, another scorpion toxin, has also been used as a BK blocker, but it inhibits some voltage-gated K^+ channels as well as the intermediate conductance calcium-activated K^+ channels (IK). Nonpeptide inhibitors include the indole diterpenes paxilline, penitrem A, and verruculogen. There are several activators of the benzimidazolone family, such as NS-1619 and NS-004, that have only moderate specificity for BK. The opener BMS-204352 may limit ischemic damage during stroke [72], while NS-8 may be useful as a treatment for incontinence [73]. BK activators may also be useful in the treatment of erectile dysfunction [74], since arousal stimulates increased BK current, causing hyperpolarization and relaxation of the cavernosal smooth muscle cell membranes.

14.2.7.3 Intermediate-Conductance Calcium-Activated K^+ Channels. Intermediate-conductance (IK) and small-conductance (SK) calcium-activated K^+ channels are both voltage-insensitive six-TM K^+ channels and derive their calcium sensitivity from calmodulin, which is constitutively bound to the channel C-terminal domain. IK channels have conductances of 20–80 pS, are found mostly in nonneuronal tissues, and are often important for secretion and volume regulation. In red blood cells, increased IK channel activity can lead to cell shrinkage that promotes the concentration and aggregation of hemoglobin S in sickle cell anemia patients [75]. In T lymphocytes, IK channels are upregulated upon mitogen stimulation [76] and maintain cytoplasmic calcium concentrations necessary for activation [77]. The importance of IK in T-cell activation could make it a potentially useful target for autoimmune diseases such as multiple sclerosis and rheumatoid arthritis [78].

The only peptide toxin that inhibits IK channels potently is charybdotoxin, but, as was mentioned above, it is not specific. The antifungal clotrimazole blocks IK at micromolar concentrations but has the undesirable property of also being a cytochrome P450 inhibitor. An analog that does not affect cytochrome activity, TRAM-34, has been reported [79] and may be a more promising pharmaceutical candidate. IK blockers have been proposed as possible treatments for sickle cell anemia [80], diarrhea, and rheumatoid arthritis [81]. As is the case with $K_v1.3$ blockers, IK inhibitors may be useful as immunosuppressants. Activators include 1-ethyl-2-benzimidazolinone (1-EBIO), a more potent analog NS309, chlorzoxanone, and zoxazolamine and may be useful in treating cystic fibrosis and vascular disorders [81].

14.2.7.4 Small-Conductance Calcium-Activated K^+ Channels. SK channels have conductances of 4–20 pS and are best known for mediating the neuronal after-hyperpolarization (AHP) of medium duration. This current activates within milliseconds and has a duration on the order of hundreds of milliseconds. Depending on channel localization, the SK AHP can regulate bursting behavior in neuronal firing, set a tonic firing frequency or instantaneous firing rate, modulate rhythmic oscillations in activity, or affect spike frequency adaptation [82]. The three SK genes, *SK1–3*, have varying sensitivities to the bee venom peptide toxin apamin, a property that has helped in distinguishing these channels electrophysiologically. Apamin-blocked AHP has been proposed to play a role in learning and memory [83], and hippocampi of Alzheimer's disease patients have been found to have reduced numbers of apamin binding sites [84]. SK activity can also regulate catecholamine release in adrenal

chromaffin cells [85]. And genetic studies have suggested SK3 involvement in schizophrenia [86] and anorexia nervosa [87].

Apamin is the most potent blocker of SK channels, and more recently, the scorpion peptide toxins scyllatoxin [88] and BmSKTx [89] have been identified as selective blockers of SK channels. Tubocurarine, a plant-derived, nonpeptide inhibitor of the nicotinic acetylcholine receptor, also blocks SK channels at the same site as apamin [90]. Dequalinium and bicuculline are other nonpeptide blockers of SK channels, but the former is a mitochondrial poison and the latter blocks γ -aminobutyric acid A (GABA_A) chloride channels. Synthesis of bisquinolinium cyclophane compounds related to dequalinium has yielded blockers such as UCL-1684, which is at least 100-fold more potent than dequalinium [91]. SK activators such as 1-EBIO, NS309, and chlorzoxanone also stimulate IK channel activity and are thought to act by increasing the interaction between SK and calmodulin [92].

14.2.7.5 KCNQ Channels. Channels of the KCNQ family are voltage gated, activate slowly, and play critical roles in cardiac, neuronal, and auditory function. Mutations in four of the five KCNQ channels (KCNQ1–4) underlie genetic disorders in humans. The first member of the family, KCNQ1, was cloned as a gene associated with long-QT syndrome type 1 [93]. KCNQ1, coassembled with KCNE1, was subsequently identified as the slow delayed-rectifier current of the cardiac action potential. KCNQ1 was later also found to form a prominent current in colonic crypt cells (with KCNE3) [94] that mediates intestinal chloride homeostasis and to modulate potassium recycling in the inner ear (with KCNE1) [95].

Long-QT syndrome type 1 is caused by mutations in either KCNQ1 or KCNE1 that lead to nonfunctional or smaller currents than wild type. These mutations are located throughout the channel [96]. The reduced channel activity leads to a prolongation of the repolarization phase of the cardiac action potential and lengthening of the QT phase of the electrocardiogram. The result can be torsade de pointes, a life-threatening arrhythmia. Autosomal-dominant LQT1, or Romano–Ward syndrome, is the result of dominant negative mutations in KCNQ1 or KCNE1, while the rarer Jervall–Lange–Nielsen syndrome is recessive and causes both LQT1 and congenital bilateral deafness. Deafness results from a failure of mutant channels to maintain high endolymph K^+ concentration. Auditory stimulation leads to potassium influx into hair cells from the endolymph, followed by K^+ exit from the basal side of hair cells and recycling to the endolymph through the stria vascularis. This last step in recycling occurs through KCNQ1/KCNE1 channels, so reduced channel activity leads to reduced endolymph potassium levels and reduced endolymph potential, which diminishes sensitivity to auditory stimuli. Potassium leaves hair cells through KCNQ4 channels on the basal side of the outer hair cell membrane [97], and a loss of this channel's function can lead to outer hair cell degeneration [98]. KCNQ4 is expressed almost exclusively in the inner ear, and mutations in this channel cause nonsyndromic autosomal dominant deafness-2 (DFNA-2) [99]. Several DFNA-2-associated mutations in KCNQ4 cluster around the pore region [100].

Two other members of the KCNQ family, KCNQ2 and KCNQ3, make up the M current, a neuronal current that is activated subthreshold and inhibited by muscarinic acetylcholine receptor activation and affects neuronal excitability. While KCNQ2 and KCNQ3 expressed alone produce relatively small currents, together they form

channels with over 10 times the current expected from summing their individual conductances [101]. In addition to M_1 muscarinic receptors, other receptors that can mediate M-current inhibition include B_2 bradykinin receptors, substance P, and luteinizing hormone–releasing receptors [102]. This coupling is a way for neurotransmitters to excite the postsynaptic membrane by inhibiting a potassium conductance that resists excitation. While knockout of KCNQ2 is lethal, a mouse with a dominant-negative KCNQ2 restricted to neurons has increased hippocampal pyramidal neuron excitability and reduced spike frequency adaptation, spontaneous seizures, and behavioral hyperexcitability [103].

Mutations in KCNQ2 and KCNQ3 are associated with a seizure disorder in neonates, benign neonatal familial convulsion (BNFC), and predispose affected individuals to epilepsy later in life. BNFCs caused by KCNQ2/3 mutations can be the result of relatively modest (25%) reductions in current [104]. Mutations that cause loss of channel function in BNFCs include pore mutations and frame-shift truncations of KCNQ2 and KCNQ3 that yield nonfunctional channels and do not act as dominant negatives [96]. KCNQ4 and KCNQ5 can also coassemble with KCNQ3 and may contribute to the diversity of M currents found in the nervous system [105].

The cardiac I_{Ks} and the neuronal M current are the two major pharmaceutical targets in the KCNQ family, and there are specific pharmacologies for each. Several antiarrhythmic drugs can block KCNQ1/KCNE1 complexes selectively, particularly the chromanols HMR1556 and chromanol 293B, and can prolong the cardiac action potential and block ventricular tachycardia by prolonging I_{Ks} [106]. These blockers both are enantioselective, (–)3*R*,4*S* being the potent enantiomer in each case [107], and more potently inhibit KCNQ1/KCNE1 complexes than KCNQ1 tetramers [108, 109]. Benzodiazapines such as L-768673 and L-7 also block I_{Ks} [110]. Mefenemic acid and the chloride channel blocker DIDS nonspecifically activate KCNQ1.
